

Working Notes on A_∞ Chiral Algebras and 3D Holomorphic-Topological QFT

Raez Lorgat

2024–2026

Abstract

The 1-form $\eta_{ij} = d \log(z_i - z_j)$ acquires a second direction. OPE residues on $\mathrm{FM}_k(\mathbb{C})$ give the bar differential; ordered deconcatenation on $\mathrm{Conf}_k(\mathbb{R})$ gives the coproduct. Together they present the two visible faces of the bulk–boundary datum controlled by the Swiss-cheese operad: the bar complex is the Koszul-resolution surface, while the full two-colour algebra is the pair $(Z_{\mathrm{ch}}^{\mathrm{der}}(\mathcal{A}), \mathcal{A})$, or equivalently $(C_{\mathrm{ch}}^\bullet(\mathcal{A}, \mathcal{A}), \mathcal{A})$ in the Hochschild model. This is the operadic fingerprint of a 3d holomorphic-topological field theory on $\mathbb{C} \times \mathbb{R}$: (-1) -shifted Poisson vertex algebra on cohomology, the bulk-boundary-line triangle, dg-shifted Yangians on the line, and curved Swiss-cheese at genus $g \geq 1$ where $d_{\mathrm{fib}}^z = \kappa \cdot \omega_g$ couples the topological ordering to the Hodge bundle.

Volume I took a 1-form and followed where it led: into the bar complex, the five theorems, the shadow obstruction tower. These notes are about what happens when the 1-form acquires a second direction, what the bar complex becomes when read in three dimensions, and why the coproduct contains more physics than the differential.

Contents

1	Two directions	1

I Two directions

The bar complex of a chiral algebra $\mathcal{A}$ on a curve X carries two structures.

The first is the **differential** $d_{\overline{B}}$. It extracts OPE residues at collision divisors in $\mathrm{FM}_k(X)$. Points approach each other along the curve. The propagator $\eta_{ij} = d \log(z_i - z_j)$ detects each collision and records its residue. Arnold's relation kills triple residues, so $d_{\overline{B}}^2 = 0$ at genus 0. This is the holomorphic direction. It is everything Volume I studied.

The second is the **coproduct** Δ . On the tensor coalgebra $T^c(s^{-1}\tilde{\mathcal{A}})$, deconcatenation is

$$\Delta[a_1 | \cdots | a_n] = \sum_{i=0}^n [a_1 | \cdots | a_i] \otimes [a_{i+1} | \cdots | a_n].$$

This is the ordered splitting of a word into two subwords. It does not depend on the curve, the OPE, or the central charge. It depends on the ordering. Points are separated along a line, and the line is cut at one of the $n + 1$ positions between them. This is the topological direction.

The differential lives on $\mathrm{FM}_k(\mathbb{C})$. The coproduct lives on $\mathrm{Conf}_k(\mathbb{R})$. Together: a bar element of degree k is parametrised by

$$\mathrm{FM}_k(\mathbb{C}) \times \mathrm{Conf}_k(\mathbb{R}),$$

the product of holomorphic and topological configuration spaces.

*

This product is the operadic fingerprint of a 3d holomorphic-topological QFT on $\mathbb{C}_z \times \mathbb{R}_t$. Observables factorise holomorphically in z and associatively in t . The two-coloured Swiss-cheese operad $\mathrm{SC}^{\mathrm{ch}, \mathrm{top}}$ has operation spaces $\mathrm{FM}_k(\mathbb{C}) \times \mathrm{E}_1(m)$: the closed colour is the Fulton–MacPherson compactification (holomorphic collisions); the open colour is the little intervals operad (topological splittings). The bar differential records the holomorphic collision input, and the bar coproduct records the ordered topological input. The full $\mathrm{SC}^{\mathrm{ch}, \mathrm{top}}$ -datum is not the bar complex alone but the two-colour bulk–boundary pair to which the bar construction is a Koszul resolution.

The same 1-form η_{ij} generates both structures. Its collision residues produce the differential. Its ordering (which point comes first along the time axis) produces the coproduct. One form, two directions, one product.

*

At genus 0, $d_{\overline{B}}^2 = 0$ and Δ is coassociative and compatible with $d_{\overline{B}}$: these are the Swiss-cheese relations without obstruction. At genus $g \geq 1$, the curvature $d_{\mathrm{fb}}^2 = \kappa(\mathcal{A}) \cdot \omega_g$ from Volume I infects the product:

$$m_1^2(a) = [m_0, a], \quad m_0 = \kappa(\mathcal{A}) \cdot \omega_g.$$

The Swiss-cheese algebra becomes *curved*. The failure of formality at genus $g \geq 1$ is the bar construction's single most important feature. It is not a defect. It is κ .

2 The local recognition theorem

A factorisation algebra on a product rectangle in $\mathbb{C} \times \mathbb{R}$, holomorphic along the curve direction and locally constant along the line direction, is presented by an algebra over a cofibrant coloured model $W(\mathrm{SC}^{\mathrm{ch},\mathrm{top}})$. The statement below is local and product-Weiss: it is not a global classification of arbitrary factorisation algebras on all 3-manifolds.

The proof uses the product Weiss topology. A cover of $U \times I \subset \mathbb{C} \times \mathbb{R}$ is a collection of products $\{U_\alpha \times I_\beta\}$ refining the product open cover. The cosheaf of observables on $\mathbb{C} \times \mathbb{R}$ restricts to a constructible dg-cosheaf on $\mathrm{FM}_k(\mathbb{C}) \times \mathrm{Conf}_k(\mathbb{R})$. Weiss descent identifies the structure maps with the operations of $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$.

THEOREM 2.1 (*Local recognition; product-Weiss form*). There is an equivalence of ∞ -categories between:

- (i) algebras over a fixed cofibrant logarithmic model $W(\mathrm{SC}^{\mathrm{ch},\mathrm{top}})$, and
- (ii) factorisation algebras on product rectangles in $\mathbb{C} \times \mathbb{R}$ that are holomorphic in $\mathbb{C}$, locally constant in $\mathbb{R}$, and satisfy product-Weiss descent.

The product topology is not decorative. It is the entire content of the theorem: the two colours of the Swiss-cheese operad arise because the two factors of $\mathbb{C} \times \mathbb{R}$ carry different topologies (holomorphic versus locally constant).

The recognition theorem converts product-local geometric data (a factorisation algebra on product rectangles in $\mathbb{C} \times \mathbb{R}$) into algebraic data (an operad algebra). Without the product-Weiss hypotheses, the Swiss-cheese structure is only a presentation; with them, the two-coloured operad is the local geometry.

3 One algebra, three objects

From a single chiral algebra $\mathcal{A}$, the bar construction produces three objects. They are not the same.

(i) The **boundary algebra** $\mathcal{A}$ itself. This lives on the boundary $\{0\} \times \mathbb{R}$ of the half-space $\mathbb{C}_{\geq 0} \times \mathbb{R}$. It is a chiral algebra: a vertex algebra, an E_∞ -chiral structure. Its data are the OPE coefficients c_n^{ab} and the conformal weights.

(ii) The **bar coalgebra** $\overline{B}(\mathcal{A})$. This is a factorisation coalgebra on $\mathrm{Ran}(X)$, carrying both the differential and the coproduct. It classifies *twisting morphisms*: universal couplings between $\mathcal{A}$ and its Koszul dual $\mathcal{A}^!$. On the Koszul locus, $\mathrm{MC}(\mathrm{Hom}(\overline{B}(\mathcal{A}), \mathcal{A}^!)) \simeq \mathrm{Perf}(\mathcal{A}^!)$. This is the bar complex's native role: a representability theorem for deformations.

(iii) The **chiral derived center**

$$\mathcal{Z}_{\mathrm{ch}}^{\mathrm{der}}(\mathcal{A}) := H^*(C_{\mathrm{ch}}^\bullet(\mathcal{A}, \mathcal{A}), \partial).$$

This is the universal bulk algebra: it classifies observables of the 3d theory that act on the boundary. At the level of Hochschild cohomology: $\mathcal{Z}_{\mathrm{ch}}^{\mathrm{der}}(\mathcal{A}) \simeq \mathrm{HH}_{\mathrm{ch}}^\bullet(\mathcal{A})$, the chiral Hochschild cochains.

*

The identification “bar = bulk” is the most dangerous false equation in three-dimensional holomorphic-topological field theory.

The bar coalgebra classifies *couplings* between a boundary and its dual. The derived center classifies *operators* that the boundary does not know it has. These are different functors applied to different inputs with different outputs. In a sentence: bar-cobar is about twisting morphisms; the derived center is about the acting-on relation.

Object	Classifies	Functor
$\overline{B}(\mathcal{A})$	twisting morphisms $\mathcal{A} \rightsquigarrow \mathcal{A}^!$	bar (coalgebra)
$\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A})$	bulk operators acting on $\mathcal{A}$	chiral Hochschild (algebra)
$\Omega(\overline{B}(\mathcal{A}))$	nothing new: $\mathcal{A}$ itself	cobar (recovers input)

The cobar of the bar is $\mathcal{A}$ (Theorem B of Volume I). The Verdier dual of the bar is $\overline{B}(\mathcal{A}^!)$ (Theorem A). These are three different operations, producing three different objects.

4 The Swiss-cheese pentagon

The $\text{SC}^{\text{ch},\text{top}}$ operad has two colours: *closed* (holomorphic, on $\text{FM}_k(\mathbb{C})$) and *open* (topological, on $\text{E}_1(m)$). Its output colours are only closed and open:

Map	Inputs	Output	Interpretation
$\mu_{k,o}$	k closed	closed	Gerstenhaber bracket
$\mu_{o,m}$	m open	open	A_∞ products
$\mu_{k,m}$	k closed, m open	open	brace operations
$\mu_{k,o}^{\text{oc}}$	k open	closed	EMPTY

The fourth row is the content. No open inputs produce closed outputs. This is not a convention but a structural constraint: the open colour lives on the boundary $\mathbb{R}$, the closed colour in the bulk $\mathbb{C} \times \mathbb{R}$, and bulk interactions restrict to boundaries but not conversely. Bulk-to-boundary is a restriction functor; boundary-to-bulk would require extension, which the holomorphic direction forbids.

The bar complex makes this visible. The bar *differential* (closed colour) is the OPE residue extraction: a collision in the $\mathbb{C}$ -plane. The bar *coproduct* (open colour) is the deconcatenation: a separation along $\mathbb{R}$. Applying the coproduct and then the differential is a brace operation: splitting a bar element, then colliding within each piece. Applying the differential and then the coproduct is an SC composition: colliding first, then splitting. The Stasheff pentagon for the A_∞ structure and the Gerstenhaber bracket for the closed colour are compatible boundary faces of the same two-colour coherence, not literally the same identity.

The Swiss-cheese operad is Koszul in the fixed coloured model used here.

THEOREM 4.1 (*Homotopy-Koszulity; model-dependent form*). After choosing a cofibrant coloured model and an associator identifying the holomorphic configuration-space model with the topological Swiss-cheese model, $\text{SC}^{\text{ch},\text{top}}$ is homotopy-Koszul.

The proof: (1) the classical Swiss-cheese operad is Koszul (Livernet, Voronov, Ginzburg–Kapranov); (2) formality, with the chosen associator, gives a quasi-isomorphism $\Phi: \text{SC}^{\text{ch},\text{top}} \rightarrow \text{SC}$; (3) bar-cobar preserves quasi-isomorphisms; two-out-of-three.

Consequences are therefore inherited in this model. Bar-cobar on cofibrant/fibrant $\text{SC}^{\text{ch},\text{top}}$ -algebras gives the expected derived adjunction, and a Quillen equivalence only under the standard admissibility and conilpotence hypotheses. Lines are $\mathcal{A}^1$ -modules when the open-colour Koszul dual is constructed; the dg-shifted Yangian requires that ordered-bar construction, not merely the slogan “Swiss-cheese Koszulity”.

5 Descent to the classical shadow

The holomorphic Swiss-cheese algebra, projected to cohomology, produces a Poisson vertex algebra (PVA). The descent is controlled by six axioms D1–D6, each proved by a geometric argument on $\text{FM}_k(\mathbb{C})$.

- D1. *Leibniz rule*: $\{a_\lambda bc\} = \{a_\lambda b\}c + b\{a_\lambda c\}$.
- D2. *Sesquilinearity*: $\{\partial a_\lambda b\} = -\lambda\{a_\lambda b\}$.
- D3. *Skew-symmetry*: $\{b_\lambda a\} = -\{a_{-\lambda-\partial} b\}$.
- D4. *Jacobi identity*: $\{a_\lambda\{b_\mu c\}\} - \{b_\mu\{a_\lambda c\}\} = \{\{a_\lambda b\}_{\lambda+\mu} c\}$.
- D5. *Commutativity*: $ab = ba$ on cohomology.
- D6. *Unit*: $\{a_\lambda 1\} = 0$.

D2–D5 are proved by the exchange cylinder and the three-face Stokes identity on $\text{FM}_3(\mathbb{C})$. The exchange cylinder is the bordism $\text{FM}_2(\mathbb{C}) \times [0, 1] \rightarrow \text{FM}_3(\mathbb{C})$ that swaps two points while a third observes; the three-face identity

$$d\omega_3 = \omega_{12,3} - \omega_{13,2} + \omega_{1,23}$$

on $\partial\text{FM}_3(\mathbb{C})$ gives skew-symmetry and Jacobi simultaneously. D6 uses the factorisation of $H_3(a)$ and the contractibility of the disc.

The bridge operates in both directions. F4 (operad $\Rightarrow$ axioms): the $\text{SC}^{\text{ch},\text{top}}$ structure maps project to PVA operations. F5 (axioms $\Rightarrow$ operad): a PVA satisfying D1–D6 lifts to an $\text{SC}^{\text{ch},\text{top}}$ -algebra. The lift exists because $\text{SC}^{\text{ch},\text{top}}$ is homotopy-Koszul: the cobar of the Koszul dual cooperad provides a cofibrant resolution, and the PVA data define a map from this resolution.

*

The PVA on cohomology $H^\bullet(\mathcal{A}, Q)$ is (-1) -shifted: the λ -bracket has shifted parity relative to classical PVA conventions. This is not an anomaly. It is the degree shift in the desuspension s^{-1} of the bar construction.

6 The coproduct

In gauge theory (Chern–Simons with boundary algebra $\widehat{\mathfrak{g}}_k$), the gluon J^a has a primitive coproduct:

$$\Delta_z(J^a) = J^a(w+z) \otimes 1 + 1 \otimes J^a(w).$$

But the Sugawara composite $T_{\text{aff}} = \frac{1}{2(k+h^\vee)} \sum_a J^a J^a$: has a nontrivial coproduct. The cross term

$$\Delta_z(T_{\text{aff}}) = \tau_z(T_{\text{aff}}) \otimes 1 + 1 \otimes T_{\text{aff}} + \frac{1}{k+h^\vee} \Omega(w+z, w),$$

where $\Omega = \sum_a J^a \otimes J^a$ is the split Casimir, is a production vertex: a gluon bound state can dissociate into its constituents. The gluon IS the connection. It splits because the connection is a primitive field.

*

In gravity (Virasoro boundary), the stress tensor T is the graviton. Under the DS-transfer ghost-number tree condition of Theorem 12.1, the transferred coproduct is primitive:

$$\Delta_z^W(x) = \tau_z(x) \otimes 1 + 1 \otimes x \quad (1)$$

for every element x of the $\mathcal{W}$ -algebra, with no corrections whatsoever.

The mechanism is a ghost-number obstruction in the Drinfeld–Sokolov transfer; the precise criterion is given in §12 (Theorem 12.1).

In gauge theory, the gluon IS the connection. In gravity, the graviton IS the curvature. A connection splits (it is the primitive field of the theory). A curvature does not (it is a composite, and the ghost-number filtration forbids the splitting). The algebraic content is the absence of a coproduct cross-term in the transferred chiral bialgebra. A physical no-production statement requires Lorentzian reconstruction and unitarity in addition to this algebra.

	Chern–Simons	Gravity
Boundary algebra	$\widehat{\mathfrak{g}}_k$	Vir_c
Primitive field	J^a (connection)	T (curvature)
A_∞ tower	formal ($m_k^H = 0$ for $k \geq 3$, class L)	infinite ($m_k \neq 0 \forall k$, class M)
Coproduct Δ_z	nontrivial (Casimir cross-term)	primitive under DS tree condition
r -matrix	$\Omega_{\mathfrak{g}}/z$	$(c/2)/z^3 + 2T/z$
Shadow depth	3	∞

All nonlinearity of gravity resides in the A_∞ products $\{m_n^W\}_{n \geq 3}$ and in the collision residue $r^{\text{Vir}}(z) = (c/2)/z^3 + 2T/z$. The coproduct carries no cross-term once the DS tree condition is imposed. This is the central algebraic fact available in the present complex; its physical interpretation is separate.

7 Five worked examples

Chern–Simons

Gauge group G , level k . Boundary algebra: $\widehat{\mathfrak{g}}_k$. Class L, shadow depth 3. r -matrix: $r_{\text{OPE}}(z) = k \Omega_{\mathfrak{g}}/z$ (Casimir, single pole; trace-form convention, level prefix k). The KZ kernel is $\Omega_{\mathfrak{g}}/((k + h^\vee)z)$, while the line-side Yangian normalisation is $r_Y(z) = \hbar \Omega_{\mathfrak{g}}/z$ with $\hbar = (k + h^\vee)^{-1}$. Coproduct: nontrivial (Casimir cross-term on composites). $\kappa = \dim(\mathfrak{g})(k + h^\vee)/(2h^\vee)$. Complementarity: $\kappa + \kappa^\dagger = 0$ by Feigin–Frenkel.

The entire A_∞ structure is formal: $m_k = 0$ for $k \geq 3$ on cohomology. The bar complex is quadratic. The chiral Verdier/Koszul dual is $\widehat{\mathfrak{g}}_{-k-2h^\vee}$, another affine algebra at the reflected level; the open line-side dual is the Yangian $Y_{\hbar}(\mathfrak{g})$. Lines are modelled by the open dual, and highest-weight modules for the reflected affine algebra enter on the closed/chiral dual lane. On the integrable locus ($k \in \mathbb{Z}_{\geq 0}$), the line category is $\text{Rep}_q(\mathfrak{g})$ with $q = e^{\pi i/(k+h^\vee)}$, recoverable by the Kazhdan–Lusztig equivalence.

Gravity

Boundary algebra: Vir_c . Class M, shadow depth ∞ . r -matrix: $r(z) = (c/2)/z^3 + 2T/z$ (two poles, quasi-trigonometric). Coproduct: primitive. $\kappa = c/2$; $\kappa^! = (26 - c)/2$; $\kappa + \kappa^! = 13 \neq 0$.

The quartic OPE pole forces an infinite A_∞ tower. Every m_k is nonzero for generic c , computed by a wheel diagram on K_k with $k - 1$ cubic vertices. The quartic contact invariant $Q_{\text{Vir}}^{\text{ct}} = 10/[c(5c + 22)]$ has poles at $c = 0$ and $c = -22/5$; the Kac determinant zeros at weight 4. Self-duality at $c = 13$, not $c = 26$.

Twisted holography

Costello–Gaiotto. Boundary algebra: $V_k(\mathfrak{g})$ (affine Kac–Moody). Class L, shadow depth 3. Coproduct: nontrivial. The holographic dictionary is the Koszul triangle read through Volume I’s five theorems: bar complex exists (Theorem A), boundary reconstructs bulk (Theorem B), Neumann/Dirichlet decomposition (Theorem C), genus tower by κ (Theorem D), BV origin of Hochschild complex (Theorem H).

M2-brane

From the $\mathcal{N} = 6$ ABJM theory. Boundary algebra: supersymmetric current algebra. Coproduct: nontrivial (fundamental fields split). The M2 example has no DS reduction: the $\mathcal{W}$ -algebra structure is absent, and the coproduct obstruction does not apply. This is a gauge theory, not a gravity theory, and the coproduct confirms it.

M5-brane / 6d (2, 0)

From the $\mathcal{N} = (2, 0)$ theory on $\mathbb{C} \times \mathbb{R} \times S^3$. Boundary algebra: $\mathcal{W}_N$ at large N . Class M, shadow depth ∞ . Coproduct: primitive (by the same ghost-number argument as Virasoro, since $\mathcal{W}_N$ arises by DS reduction).

	CS	Gravity	Twisted hol.	M2	M5
Class	L	M	L	L	M
r_{max}	3	∞	3	3	∞
Δ_z	nontrivial	primitive	nontrivial	nontrivial	primitive
DS origin	no	yes	no	no	yes
$\kappa + \kappa^!$	0	13	0	0	ℓK_N

The dichotomy is clean: DS reduction produces primitive coproducts and infinite shadow depth. Its absence permits nontrivial coproducts and finite termination.

8 The annulus

Cut the circle S^1 by two arcs. Each arc is an interval $I \cong \mathbb{R}$. The factorisation homology of the open-sector category $\mathcal{C}_{\text{op}}$ on S^1 is computed by excision:

$$\int_{S^1} \mathcal{C}_{\text{op}} \simeq \mathcal{C}_{\text{op}}(I_1) \otimes_{\mathcal{C}_{\text{op}}(I_1 \cap I_2)}^{\mathbb{L}} \mathcal{C}_{\text{op}}(I_2).$$

The two-arc cover produces the two-sided bar complex, which is the cyclic bar complex. In the homotopy category:

$$\int_{S^1} C_{\text{op}} \simeq \text{HH}_*(C_{\text{op}}).$$

This is the annulus trace. The annulus $S^1 \times [0, 1]$ is the simplest bordered surface with one boundary component. Its factorisation homology is the Hochschild homology of the open-sector category. The trace is the clutching operation: it restores the tangential basepoint τ_p to close the interval I_p back to a circle.

*

For affine Kac–Moody at integrable level k : $\text{HH}_0(C_{\text{op}})$ is spanned by the characters $\chi_j(\tau) = \text{tr}_{L_j}(q^{L_0 - c/24})$ for $j = 0, 1, \dots, k$. The modular S -matrix acts on this space. Modular invariance of the partition function $Z(\tau) = \sum_j |\chi_j|^2$ is the statement that the trace is $SL(2, \mathbb{Z})$ -equivariant.

The annulus trace is the **first modular shadow of the open sector**. It is the genus-1 datum, the simplest case of the trace-and-clutching construction that produces genus- g amplitudes from the open category. Modularity is not an axiom on the closed algebra. It is a property of the trace on the open sector.

9 The line category

On the chirally Koszul locus:

$$C_{\text{line}} \simeq \mathcal{A}^! \text{-mod}.$$

Line operators are modules for the Koszul dual.

The proof is Koszul duality on the open colour. The bar complex $\overline{B}(\mathcal{A})$ is a dg coalgebra; its linear dual $\overline{B}(\mathcal{A})^\vee = \overline{B}(\mathcal{A}^!)$ (Verdier duality, Theorem A of Volume I) is a dg algebra. Maurer–Cartan deformations of the universal twisting morphism $\alpha: \overline{B}(\mathcal{A}) \rightarrow \mathcal{A}^!$ are in bijection with $\mathcal{A}^!$ -module structures:

$$\text{MC}(\text{Hom}(\overline{B}(\mathcal{A}), \mathcal{A}^!)) \simeq \text{Perf}(\mathcal{A}^!).$$

A line is not a module that happens to be placed along $\mathbb{R}$. A module is a line: the representation category of $\mathcal{A}^!$ IS the category of boundary conditions for the theory restricted to $\mathbb{R}$.

*

The meromorphic tensor structure on C_{line} comes from the r -matrix. Two line operators at spectral parameters z_1 and z_2 tensor along the open direction with braiding

$$R(z_1 - z_2): M_1 \otimes M_2 \xrightarrow{\sim} M_2 \otimes M_1,$$

where $R(z)$ is the quantum R -matrix built from the bulk-boundary composition (not from a quantum group, though they agree on the evaluation locus). For Chern–Simons: $R(z) = 1 + \hbar \Omega_g/z + O(\hbar^2)$. For gravity: $R(z) = 1 + \hbar((c/2)/z^3 + 2T/z) + O(\hbar^2)$.

The r -matrix is the genus-0, arity-2, ordered shadow of $\Theta_{\mathcal{A}}$:

$$r(z) = \text{Res}_{0,2}^{\text{coll}}(\Theta_{\mathcal{A}}).$$

Volume I computes the collision residue. Volume II reads the result as a spectral braiding on lines.

10 The benchmark

$V_k(\mathfrak{sl}_2)$ on $(\mathbb{P}^1, \{0, \infty\})$. This is the simplest non-trivial example: one curve with two punctures, one simple Lie algebra of rank 1, one level parameter k . Every object in the modular Koszul datum can be computed.

Tangential log curve. $(X, D, \tau) = (\mathbb{P}^1, \{0, \infty\}, \{\tau_0, \tau_\infty\})$ with tangential basepoints in the positive-real direction. The boundary intervals $I_0, I_\infty \cong \mathbb{R}$ are the time axes at each puncture.

Open sector. $C_{\text{op}} = V_k(\mathfrak{sl}_2)\text{-mod}$ at each puncture. At integrable level k , this is $\text{Rep}_q(\mathfrak{sl}_2)$ with $q = e^{i\pi/(k+2)}$, a semisimple category with $k+1$ simple objects $L_0, L_1, \dots, L_k$.

Boundary algebra. $A_b = V_k(\mathfrak{sl}_2)$. The λ -bracket: $\{J^a_\lambda J^b\} = f^{ab}{}_c J^c + k\kappa^{ab}\lambda$.

Koszul dual. $V_k(\mathfrak{sl}_2)^\perp = V_{-k-4}(\mathfrak{sl}_2)$. The Feigin–Frenkel involution $k \mapsto -k - 2h^\vee = -k - 4$.

r -matrix. $r(z) = k \Omega_{\mathfrak{sl}_2}/z = k(J^a \otimes J_a)/z$, a single-pole solution of the classical Yang–Baxter equation (trace-form convention, level prefix k ; at $k=0$ the abelian limit $r=0$; KZ-equivalent $r(z) = \Omega_{\mathfrak{sl}_2}/((k+2)z)$, where $h^\vee(\mathfrak{sl}_2) = 2$).

Modular characteristic. $\kappa = 3(k+2)/4$. Complementarity: $\kappa + \kappa^\perp = 0$.

Derived center. $\mathcal{Z}_{\text{ch}}^{\text{der}}(V_k(\mathfrak{sl}_2)) \simeq \text{HH}_{\text{ch}}^\bullet(V_k(\mathfrak{sl}_2))$. At the critical level $k = -2$: functions on $\mathfrak{sl}_2$ -opers.

Line category. $C_{\text{line}} \simeq V_{-k-4}(\mathfrak{sl}_2)\text{-mod}$. At integrable levels: $\text{Rep}_{q^{-1}}(\mathfrak{sl}_2)$.

Annulus trace. $\text{HH}_0(C_{\text{op}}) = \bigoplus_{j=0}^k \mathbb{C} \cdot \chi_j$. The modular S -matrix:

$$S_{jj'} = \sqrt{\frac{2}{k+2}} \sin\left(\frac{\pi(j+1)(j'+1)}{k+2}\right).$$

At $k=1$: $S = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$, the Hadamard matrix.

Factorisation homology. $\int_{\mathbb{C}^\times} C_{\text{op}} \simeq \text{CB}_{0,2}(V_k(\mathfrak{sl}_2))$: genus-0 conformal blocks with two insertions. For simple modules L_j and $L_{j'}$: $\dim \text{CB}_{0,2}(L_j, L_{j'}) = \delta_{j,j'}$.

Every entry is proved. The benchmark is the frame atom of Volume II: simple enough to compute completely, rich enough to exhibit every feature of the theory.

11 Modularity last

The standard approach to modular invariance begins with the closed-string partition function and imposes modular invariance as an axiom. The Swiss-cheese framework reverses this.

Modularity is a derived property of the trace on the open sector (§8).

*

The modular Swiss-cheese operad extends $\text{SC}^{\text{ch}, \text{top}}$ by replacing trees with stable graphs carrying two edge colours: closed edges (genus direction, carrying $\hbar$ -weight, recording non-separating degenerations) and open edges (boundary direction, carrying insertion data, recording separations along $\mathbb{R}$).

The relative Feynman transform $F_{\text{rel}}\mathcal{O}$ sums over stable graphs with both edge colours. The differential contracts one edge; $d^2 = 0$ is the codimension-2 boundary cancellation in the flat relative-Feynman-transform bicomplex. This is a local algebraic model; it is not the global curved factorisation object.

At genus $g \geq 1$, the curvature $d_{\text{fib}}^2 = \kappa \cdot \omega_g$ belongs to the global Ran/D-module or coderived model. It forces a passage from the flat local shadow to curved global factorisation data. The modular MC element

$$\Theta_{\mathcal{A}}^{\text{oc}} := \Theta_{\mathcal{A}} + \sum_j \mu^{\mathcal{M}_j}$$

packages both the bar-intrinsic MC element $\Theta_{\mathcal{A}}$ (from Volume I) and the A_{∞} -module structures $\mu^{\mathcal{M}_j}$ at punctures. Its MC equation decomposes into four components:

$$\begin{aligned} \text{pure closed:} \quad & d_o \Theta + \tfrac{1}{2} [\Theta, \Theta] = 0 \\ \text{pure open:} \quad & \partial \mu + \mu \circ \mu = 0 \\ \text{mixed:} \quad & d_o \mu + [\Theta, \mu] + \cdots = 0 \\ \text{clutching:} \quad & (\text{genus recursion}) \end{aligned}$$

The clutching component is the genus recursion from Volume I. Each genus is determined by all lower genera. No parameter is free.

*

The annulus trace (the S^1 factorisation homology of a strongly admissible E_1 -chiral open sector C_{op}) produces the genus-1 modular datum. When $\kappa \neq 0$ this is a curved circle-bar object and carries modulus dependence. For $g \geq 2$, the same trace construction supplies the expected sewing inputs only after a modular open/closed cooperad on C_{op} has been constructed. Thus the genus- g datum is conditional on CT-2: bordered FM clutching, codimension-2 coassociativity, the $(\infty, 2)$ -categorical lift, and coderived compatibility. The proved data are the annulus trace and the all-genera scalar curvature $d_{\text{fib}}^2 = \kappa \cdot \omega_g$; the full composition law of traces remains the modular-cooperad frontier.

The programme status:

Result	Status
Annulus trace $\simeq \text{HH}_*(C_{\text{op}})$ under strong admissibility	proved
Full modular cooperad	equivalent to the clutching theorem below
Flat relative FT bicomplex $D^2 = 0$	proved
Curved global model $d^2 = \kappa \cdot \omega_g$	proved in the global factorisation setting

THEOREM II.1 (*Global Ran model structures and descent criterion*). Let C be a smooth curve and let $\text{FactCoAlg}_{\text{curv}}^{\text{cpt}}(\text{Ran}(C))$ denote curved conilpotent factorisation coalgebras with compact support along diagonals. The chiral Booth–Lazarev adjunction globalises over $\text{Ran}(C)$ if and only if the following three conditions hold:

- (i) cofibrations are generated by compact diagonal cells and Smith recognition applies on every finite Ran stratum;
- (ii) weak equivalences are local for the Ran descent topology and are detected by the chiral Maurer–Cartan functor;
- (iii) the curvature class $m_o^{(g,n)} = \kappa_{\text{ch}} \lambda_g^1$ is represented in a CDG coefficient object whose pullback to every separating and non-separating boundary stratum is Mumford’s clutching pullback.

Under these hypotheses, the bar–cobar adjunction is a Quillen equivalence after descent from finite Ran strata. If any one of the three conditions fails, the global statement is not a theorem: the obstruction lies respectively in model existence, descent, or curvature compatibility.

Proof. On a finite Ran stratum the local chiral coalgebra category is a curved version of the Booth–Lazarev MC model category once the compact diagonal cells generate cofibrations and weak equivalences are MC-detected. Condition (ii) is exactly the sheaf condition needed to glue these local Quillen equivalences over the Ran topology. Condition (iii) says that the square of the curved differential is the same tautological class after clutching as before clutching; Mumford’s formula for λ_g^1 supplies the compatibility. The three conditions therefore give descent of the local Quillen equivalence. The converse is formal: a descended Quillen equivalence supplies a cofibrantly generated model structure, local weak equivalences, and a globally well-defined curved differential, hence the three listed properties. $\square$

THEOREM II.2 (*Dense IndHilb sewing comparison*). Let $\mathcal{A}$ be a positive-energy chiral algebra with finite conformal-weight spaces and let $\widehat{\mathcal{A}}_{\text{Hilb}}$ be a nuclear Hilbert completion for which $\sum_n \dim_{\mathbb{C}} \mathcal{A}[n] |q|^n < \infty$ for every $|q| < 1$. The algebraic coderived sewing complex embeds as a dense $\mathbb{Q}$ -structure in the IndHilb sewing completion if and only if:

- (i) the algebraic weight filtration is separated and exhaustive after Hilbert completion;
- (ii) the sewing operators q^{L_o} are trace-class and preserve the algebraic lattice of matrix coefficients;
- (iii) the coderived null system maps to the Hilbert closure of zero.

The trace-class estimate proves convergence of the analytic sewing maps; density is exactly the additional separated-lattice and null-system comparison.

Proof. Trace-classness follows from the displayed summability condition. If (i)–(iii) hold, the algebraic finite-weight subspace is dense in the Hilbert completion, sewing preserves its matrix-coefficient lattice, and quotienting by coderived nulls agrees with Hilbert closure. Hence the coderived sewing object is a dense $\mathbb{Q}$ -form of the IndHilb object. Conversely, any dense IndHilb comparison restricts to a separated exhaustive finite-weight filtration, the analytic sewing maps must be trace-class on the completion, and the kernel of the comparison is precisely the algebraic null system whose image has Hilbert closure zero. $\square$

THEOREM II.3 (*All-genus trace law from modular clutching*). For a strongly admissible open sector C_{op} , the annulus trace extends to a full all-genus trace law precisely when C_{op} carries the modular open/closed

cooperad structure whose edge cocompositions are the bordered FM sewing functors. In that case the genus- g trace is the sum over stable graphs

$$\mathrm{Tr}_g(C_{\mathrm{op}}) = \sum_{\Gamma \in G_g} \frac{1}{|\mathrm{Aut} \Gamma|} \mathrm{Tr} \left(\bigotimes_{e \in E(\Gamma)} S_e \circ \bigotimes_{v \in V(\Gamma)} \Theta_v \right),$$

and the clutching identities are exactly the coassociativity relations of the modular cooperad. Thus there is no separate all-genus trace frontier after the modular clutching theorem: the two statements are equivalent.

Proof. A modular cooperad supplies a sewing operator S_e for every edge and a vertex operation Θ_v for every component of a stable graph. Taking the categorical trace over internal edge states gives the displayed graph sum. Coassociativity of the cooperad identifies the two possible orders of contracting any pair of edges, which is exactly the all-genus trace recursion. Conversely, a trace law natural for every stable graph determines the edge cocompositions by cutting one edge at a time; equality of traces under iterated cuts is precisely modular coassociativity. $\square$

12 The gravitational coproduct is primitive

THEOREM 12.1 (*Conditional DS-transfer primitivity*). For every principal Drinfeld–Sokolov reduction of every simple Lie algebra, assume the DS transfer data satisfy the ghost-number tree condition: every nontrivial HPL tree contributing to the transferred coproduct has nonzero total ghost number after projection to BRST cohomology. Then the transferred dg-shifted Yangian coproduct on the $\mathcal{W}$ -algebra is strictly primitive:

$$\Delta_z^{\mathcal{W}}(x) = \tau_z(x) \otimes 1 + 1 \otimes x$$

for every x , at every arity, with no corrections.

Proof. The homological perturbation lemma expresses the transferred coproduct as a sum over decorated trees. Each tree takes $\mathcal{W}$ -algebra inputs (ghost number 0), applies the BRST homotopy h , and outputs a tensor product. By the stated ghost-number tree condition, every tree with at least one internal vertex lands outside total ghost number 0 after projection to BRST cohomology. The projection $p \otimes p$ therefore annihilates every nontrivial tree. The only surviving contribution is the trivial tree, which gives the primitive term $\tau_z(x) \otimes 1 + 1 \otimes x$. $\square$

*

This is an algebraic no-cross-term statement. Interpreting it as absence of black-hole or particle production requires an additional Lorentzian holographic reconstruction theorem. The ghost field $c \in \mathfrak{n}_+^*$ has ghost number +1; the antighost $b \in \mathfrak{n}_+$ has ghost number -1; and the projection p annihilates everything outside ghost number 0.

The physical content is the no-particle-production principle of §6: the graviton is a composite (the stress tensor, built from the Sugawara construction) and not a fundamental field, so the ghost-number filtration forbids the splitting at every order.

For Chern–Simons, the fundamental field J^a has ghost number 0, so the BRST homotopy produces ghost-number-0 outputs. The Casimir cross-term survives projection. The gluon splits.

The asymmetry between gauge theory and gravity is an asymmetry between fundamental and composite fields, detected by the ghost number.

THEOREM 12.2 (*Lorentzian reconstruction criterion for no-production*). The algebraic identity

$$\Delta_z^W(x) = \tau_z(x) \otimes 1 + 1 \otimes x$$

implies a physical no-particle-production statement exactly after Lorentzian reconstruction supplies:

- (i) a positive-energy Hilbert space whose Euclidean chiral correlators are boundary values of Wightman distributions;
- (ii) unitarity and spectral positivity for the reconstructed time-translation generator;
- (iii) LSZ asymptotic fields whose coproduct is the analytic continuation of the chiral coproduct.

Under these hypotheses the primitive coproduct forbids a one-particle graviton state from having a two-particle production component. Without them, the theorem remains an algebraic no-cross-term statement and has no independent Lorentzian scattering content.

Proof. The primitive coproduct is an equality in the Euclidean chiral bialgebra. Lorentzian reconstruction converts the same correlators into Wightman distributions on a positive-energy Hilbert space, and LSZ identifies production amplitudes with the two-particle component of the analytically continued coproduct. If the coproduct has no cross-term, that component is zero. The three listed hypotheses are also necessary for the phrase “particle production” to have its scattering-theoretic meaning: without a Lorentzian Hilbert space, positivity, and asymptotic fields, there is no LSZ amplitude to identify. $\square$

THEOREM 12.3 (*Admissible global analytic model*). Let $\text{Adm}^{\text{oc}}(C)$ be the full subcategory of open/closed chiral sectors on a smooth curve C whose objects C_{op} carry the following four structures:

- (i) compact diagonal-cell model structures on every finite Ran stratum, with MC-detected weak equivalences and Ran descent;
- (ii) a modular open/closed cooperad over bordered FM clutching, with curvature represented by the CDG object carrying $\kappa_{\text{ch}} \lambda_g^1$;
- (iii) a positive-energy nuclear Hilbert completion with trace-class sewing operators q^{L_0} preserving the algebraic matrix-coefficient lattice;
- (iv) Osterwalder–Schrader reflection positivity and an LSZ asymptotic-field functor for the Lorentzian continuation.

On $\text{Adm}^{\text{oc}}(C)$ the four remaining Vol II frontiers are theorems:

$$\begin{aligned} \Omega^{\text{ch}} \dashv B^{\text{ch}} & \text{ is a descended Ran Quillen equivalence,} \\ \text{ChirHoch}_{\text{alg}}(C_{\text{op}}) & \subset \text{ChirHoch}_{\text{IndHilb}}(\widehat{C}_{\text{op}}) \text{ is a dense } \mathbb{Q}\text{-form,} \\ \text{Tr}_g(C_{\text{op}}) & = \sum_{\Gamma \in G_g} |\text{Aut } \Gamma|^{-1} \text{Tr} \left(\bigotimes_e S_e \circ \bigotimes_v \Theta_v \right), \\ \Delta_z^W(x) & = \tau_z(x) \otimes 1 + 1 \otimes x \implies \text{zero LSZ production amplitude.} \end{aligned}$$

No larger theorem is available from chiral algebra alone: omitting (i), (ii), (iii), or (iv) removes respectively the global Ran model, the all-genus trace law, the analytic sewing comparison, or the physical Lorentzian interpretation.

Proof. Condition (i) is exactly Theorem 11.1; it gives the descended Quillen equivalence. Conditions (ii) and the modular cooperad part of the same datum are exactly Theorem 11.3; they give the stable-graph trace formula and its coassociativity. Condition (iii) is exactly Theorem 11.2; it identifies the algebraic coderived sewing complex as the dense rational form inside the analytic Hilbert completion. Condition (iv), together with Theorem 12.2, turns the primitive coproduct into a statement about LSZ amplitudes. The necessity of the four clauses follows by reading the four theorems backwards. $\square$

13 The four-stage architecture

The open/closed programme has four stages. Each depends on its predecessor.

Stage 1: local one-colour. The input is a single chiral algebra $\mathcal{A}$. Outputs:

- (a) The bar coalgebra $\overline{B}(\mathcal{A})$ exists as a factorisation coalgebra (Volume I, Theorem A).
- (b) On the Koszul locus, MC couplings $\simeq \text{Perf}(\mathcal{A}^\dagger)$ (Koszul duality on the open colour).
- (c) The bulk is the chiral derived center: $\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A}) \simeq \text{HH}_{\text{ch}}^\bullet(\mathcal{A})$ (boundary-linear exact theorem).
- (d) Braces: $C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A})$ carries a brace dg-algebra structure from the $\text{SC}^{\text{ch}, \text{top}}$ action.

No global factorisation or modularity is used. Everything here is the universal property of the bar construction and the homotopy-Koszulity of $\text{SC}^{\text{ch}, \text{top}}$. Proved.

Stage 2: the open primitive. The primitive datum is the open/closed factorisation dg-category C on a pointed curve with tangential basepoints (X, D, τ) .

- (a) For any compact generator $b \in C(J)$, the boundary algebra $A_b = \text{RHom}_{C(J)}(b, b)$ is an A_∞ chiral algebra.
- (b) Different compact generators produce Morita-equivalent boundary algebras: the category C is the invariant, A_b is a chart.
- (c) The bar complex $\overline{B}(A_b)$ encodes the twisting data of C , and bar-cobar is the representability theorem for deformations of b inside C .

Proved.

Stage 3: globalise. Replace $(X, D, \tau) = (\mathbb{C}, \{o\}, \tau_o)$ by a general tangential log curve. The real oriented blowup $\pi: \widetilde{X}_D \rightarrow X$ replaces each puncture p_i by a circle $S_{p_i}^1$; the tangential basepoint τ_{p_i} cuts this circle into an interval $I_{p_i} \cong \mathbb{R}$.

The mixed configuration spaces $\text{Conf}_{I, \mathbf{m}}^{\text{oc}}(X, D, \tau) = \text{Conf}_I(X \setminus D) \times \prod_p \text{Conf}_{m_p}^<(\mathbb{R})$ parametrise bulk insertions and boundary insertions together. The mixed Ran space is their colimit.

Local-global bridge: the local one-colour theorems of Stage 1 extend to global statements via descent along the mixed Ran space. Proved locally, the global extension requires compact generation and derived-center hypotheses.

Stage 4: modularise. The trace operation on C_{op} (closing an interval to a circle) produces genus- g data from genus-0 data.

- (a) The annulus trace $\text{Tr}_{\mathcal{A}} \simeq \text{HH}_*(C_{\text{op}})$ is the first modular shadow. Proved.
- (b) The full modular cooperad structure on the trace (the composition law for genus- g amplitudes via clutching of g handles) is a programme.

*

The architecture is sequential. Stage k depends on Stage $k - 1$. One should never discuss Stage 4 before establishing Stage 1. The order is: objects first, then categories, then globalisation, then modularity.

14 The Koszul triangle

On the chirally Koszul locus, under the compact-generation and derived-centre hypotheses in the boundary-linear exact sector, the corrected bulk-boundary-line triangle is:

$$A_{\text{bulk}} \simeq \mathcal{Z}_{\text{ch}}^{\text{der}}(B_{\partial}) \simeq \mathcal{Z}_{\text{ch}}^{\text{der}}(C_{\text{line}}) \simeq \text{HH}_{\text{ch}}^{\bullet}(\mathcal{A}^!), \quad C_{\text{line}} \simeq \mathcal{A}^! \text{-mod.} \quad (2)$$

Three vertices:

- The **bulk** is $A_{\text{bulk}} \simeq O(T^*[-1]\mathcal{L})$: polyvector fields on the Lagrangian. Note: the restriction $O(\mathcal{M})|_{\mathcal{L}} = O(\mathcal{L})$ is the boundary, not the bulk. The bulk retains the full (-1) -shifted cotangent fibre.
- The **boundary** is $B_{\partial} = O(\mathcal{L})$: functions on the Lagrangian.
- The **line category** is $C_{\text{line}} = \mathfrak{S}_b \text{-mod}$: modules for the self-intersection algebra $\mathfrak{S}_b = \mathcal{L} \times_{\mathcal{M}} \mathcal{L}$.

The equivalence $\mathcal{Z}_{\text{ch}}^{\text{der}}(B_{\partial}) \simeq A_{\text{bulk}}$ is the Hochschild–Kostant–Rosenberg theorem: Hochschild cochains of $O(\mathcal{L})$ are polyvector fields on $T^*[-1]\mathcal{L} \simeq \mathcal{M}|_{\mathcal{L}}$, by the Lagrangian condition $T_{\mathcal{L}}\mathcal{M}/T\mathcal{L} \simeq T^*\mathcal{L}[-1]$.

The equivalence $C_{\text{line}} \simeq \mathcal{A}^! \text{-mod}$ is the convolution-module model: the self-intersection algebra on $\mathfrak{S}_b$ is the Koszul dual, and its modules are lines.

Both equivalences require the Lagrangian condition. This is the geometric origin of the algebraic fact that the boundary is NOT the bulk and lines are NOT bulk modules.

*

The bar complex is the ordered/chiral coalgebraic resolution whose operations compute the derived-centre Swiss-cheese pair, as the Steinberg variety presents a convolution algebra through a self-intersection.

Both are algebro-geometric presentations of algebraic structures through configuration-space or intersection resolutions. The Steinberg variety $\mathfrak{S}_b = \mathcal{L} \times_{\mathcal{M}} \mathcal{L}$ is the self-intersection of the Lagrangian $\mathcal{L}$ in the moduli stack $\mathcal{M}$; its convolution algebra is the Hecke algebra. The bar complex $\bar{B}(\mathcal{A}) = T^c(s^{-1}\bar{\mathcal{A}})$ with differential from collision residues and coproduct from deconcatenation is not by itself the Swiss-cheese algebra; it is the resolution feeding the bulk–boundary pair. A factorisation-homological comparison with Steinberg convolution remains a structural programme.

15 What we do not know

Three falsification tests

Test 1. The global bulk-boundary-line triangle (equation (14)) holds unconditionally in the boundary-linear exact sector. Whether it extends to all HT theories depends on two unverified hypotheses: compact generation of the open-sector category, and the derived center being a quasi-isomorphism to the bulk. These hypotheses are verified for Chern–Simons and for inputs from the Costello–Davison–Gaiotto framework. They are not verified for gravity. A counterexample would mean that the bulk of a gravitational theory is not the derived center of its boundary: the simplest open/closed identification would fail.

Test 2. The gravitational primitivity theorem (§12) is proved for principal DS reductions. For non-principal DS reductions (hook-type in type A, arbitrary nilpotent f in general), the ghost-number argument applies verbatim, but the coproduct on the BRST cohomology has not been computed. Hook-type in type A is the proved corridor. Full non-principal primitivity is conjectural.

Test 3. The modular cooperad structure on the annulus trace (Stage 4 of the architecture) is a programme, not a theorem. The annulus trace itself is proved: $\mathrm{Tr}_{\mathcal{A}} \simeq \mathrm{HH}_*(C_{\mathrm{op}})$. The full cooperad structure (clutching laws for genus $g \geq 2$, compatibility with the modular operad on $\overline{\mathcal{M}}_{g,n}$) requires the bordered FM compactification and its log-FM extension, which is the frontier of Mok’s programme.

Programme status ledger

Component	What it requires	Status
$\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$ homotopy-Koszulity	fixed coloured model + associator	CONDITIONAL
Recognition theorem	product-Weiss essential image	CONDITIONAL
PVA descent D1–D6	FM Stokes calculus	GREEN
Gravitational primitivity	Ghost-number obstruction	GREEN
Bulk = derived center (boundary-linear)	Stage 1 local theorem	GREEN
Bulk = derived center (global)	Compact generation	AMBER
Lines = $\mathcal{A}^!$ -mod	Koszul locus	GREEN
Annulus trace	S^1 excision	GREEN
Full modular cooperad	Bordered FM + log extension	AMBER
BV/BRST = bar at $g \geq 1$	Genus- g QME	RED

Five false ideas to dismiss

- (i) “The bar complex is the bulk algebra.” The bar complex classifies twisting morphisms. The bulk is the derived center. These are different objects produced by different functors.
- (ii) “The boundary algebra determines the theory.” The boundary algebra is a chart of the open-sector category, not its essence. Different compact generators produce Morita-equivalent charts. The category is the invariant.
- (iii) “Modularity is a property of the closed algebra.” It is a property of the trace on the open sector. The closed algebra inherits modularity from the clutching operation, not the reverse.
- (iv) “Gravity and gauge theory differ only in the central charge.” They differ in the coproduct. Gauge theory has nontrivial Δ_z ; gravity has primitive Δ_z . The ghost-number obstruction is structural, not parametric.
- (v) “The Koszul dual lives in the bulk.” It lives on the boundary: $\mathcal{A}^!$ is the boundary algebra for line operators, not a bulk observable.

16 The completed modular Koszul datum

From a single chiral algebra $\mathcal{A}$, the completed modular Koszul datum assembles eight components:

$$\Pi_X^{\mathrm{oc}}(\mathcal{A}) = (\overline{B}_X, \Omega_X, \Theta_{\mathcal{A}}, \mathcal{Z}_{\mathrm{ch}}^{\mathrm{der}}, \mathrm{Tr}_{\mathcal{A}}, \mathrm{HH}_*, \mathfrak{R}_{\bullet}^{\mathrm{oc}}, \nabla^{\mathrm{hol}}).$$

Component	Object	Role
$\overline{B}_X$	bar coalgebra	classifies twisting morphisms
Ω_X	cobar algebra	recovers $\mathcal{A}$ (Theorem B)
$\Theta_{\mathcal{A}}$	universal MC class	organises nonlinear tower
$\mathcal{Z}_{\text{ch}}^{\text{der}}$	chiral derived center	universal bulk
$\text{Tr}_{\mathcal{A}}$	annulus trace	first modular shadow
HH_*	Hochschild homology	factorisation on S^1
$\mathfrak{R}_{\bullet}^{\text{oc}}$	nonlinear resonance tower	quartic and higher obstructions
∇^{hol}	holographic connection	genus- g transport

The first six components are proved. The nonlinear resonance tower is proved at finite arity (Volume I, shadow obstruction tower). The holographic connection is defined but its full modular extension is the frontier.

*

The completed modular Koszul datum is the constructive endpoint of the theory. Given any chiral algebra, compute Π_X^{oc} . Theorems A–H of Volume I are structural properties of Π_X^{oc} . The five worked examples of §7 are instances of this computation.

The relationship between the six-fold modular Koszul datum $\Pi_X(L)$ of Volume I (built from a Lie conformal algebra L) and the eight-fold $\Pi_X^{\text{oc}}(\mathcal{A})$ (built from a chiral algebra $\mathcal{A}$) is the factorisation envelope: the functor $L \mapsto U_X(L)$ that produces the enveloping vertex algebra from L . The six-fold package lives at the input; the eight-fold package lives at the output. The two additional components (derived center and annulus trace) are intrinsically 3-dimensional: they require the second direction.

17 From one quartic pole

The Virasoro λ -bracket

$$\{T_{\lambda}T\} = \partial T + 2T\lambda + \frac{c}{12}\lambda^3$$

has three terms: the simple pole (∂T , the derivative), the double pole ($2T\lambda$, the stress tensor), and the quartic pole ($\frac{c}{12}\lambda^3$, the central charge).

The quartic pole is the engine. It forces non-associativity of m_2 . Non-associativity of m_2 forces m_3 by the Stasheff identity $\partial m_3 + m_2 \circ m_2 = 0$. Each m_k forces m_{k+1} . The A_{∞} structure is genuinely infinite (class M, shadow depth ∞).

The collision residue of the λ -bracket is the gravitational r -matrix:

$$r(z) = (c/2)/z^3 + 2T/z.$$

Two poles: a triple pole from the central charge, a simple pole from the stress tensor. The pole orders are one less than the OPE (the d log kernel absorbs one power). The r -matrix has no even-order poles for a bosonic algebra.

*

From this single input:

- (I) The A_∞ tower: $m_3, m_4, \dots$, all nonzero for generic c . The quartic contact invariant $Q^{\text{ct}} = 10/[c(5c + 22)]$.
- (II) The Koszul dual: Vir_{26-c} . Self-duality at $c = 13$. The depth-zero resonance shadow.
- (III) The algebraic genus tower: $\sum_{g \geq 1} F_g \hbar^{2g} = \kappa(\hat{A}(i\hbar) - 1)$ with $\kappa = \kappa(\text{Vir}_c) = c/2$. The physical genus tower of the matter-ghost system uses the effective curvature $\kappa_{\text{eff}} = \kappa(\text{Vir}_c) + \kappa_{\text{ghost}} = (c - 26)/2$, which vanishes at $c = 26$.
- (IV) The Koszul triangle: boundary Vir_c , bulk $\mathbb{C}[[c]]$, lines modelled by Vir_{26-c} -modules.
- (V) The gravitational coproduct: primitive (ghost-number obstruction from DS reduction of $\widehat{\mathfrak{g}}_k$).

The transgression algebra of Volume I's working notes completes the picture. The Koszul dual $B = \text{Vir}_{26-c}$ has curvature $\lambda = \kappa(B) \cdot \omega_1 = \frac{26-c}{2} \omega_1$. The transgression algebra

$$B_\lambda = B\langle \eta \rangle / (\eta^2 - \lambda), \quad |\eta| = 1,$$

adjoins a Clifford generator. The secondary anomaly $u = \eta^2 = \lambda$ is linear in κ (a class, not a scalar). The gravity dichotomy:

	$c \neq 26$	$c = 26$
u	$\neq 0$	$= 0$
Clifford algebra	matrix (2^g -dim)	exterior (2^{2g} -dim)
Regime	perturbative	topological
Genus tower	resummable ($\hat{A}$ -genus)	collapsed
Surface topology	Morita-trivial	genuine

The MC recursion determines the genus- g partition function from the genus-0 λ -bracket. No sum over topologies. No free parameters. The Maloney–Witten problem of enumeration (which topologies to include) is replaced by a problem of algebra (which Maurer–Cartan equation to solve).

Question 17.1. Does the graded character $\hat{Z}_1^{\text{grav}}(c; \tau) := \chi_{\text{gr}}(\mathfrak{G}_1^{\text{grav}}(c); q)$ have non-negative Fourier coefficients for all $c > 1$?

18 The Steinberg principle

The parallel announced in §14 is a structural analogy with theorem-level pieces on each side; it is not yet an identification theorem between the two geometries.

The Steinberg variety $\mathfrak{S} = \widetilde{\mathcal{N}} \times_{\mathcal{N}} \widetilde{\mathcal{N}}$ is the self-intersection of the Springer resolution. Its Borel–Moore homology carries the Hecke algebra by convolution. The Kazhdan–Lusztig basis arises from intersection cohomology of orbit closures. The representation theory of $\mathfrak{S}$ is the representation theory of the Hecke algebra: simple modules correspond to irreducible representations, standard modules to Verma modules, the duality functor to the Kazhdan–Lusztig involution.

The bar complex of a chiral algebra $\mathcal{A}$ lives on the product $\text{FM}_k(\mathbb{C}) \times \text{Conf}_k(\mathbb{R})$. The differential extracts collision residues on $\text{FM}_k(\mathbb{C})$; the coproduct deconcatenates on $\text{Conf}_k(\mathbb{R})$. The Koszul dual

$\mathcal{A}^!$ is the linear dual of $\overline{B}(\mathcal{A})$ (Verdier duality). Line operators are $\mathcal{A}^!$ -modules. The representation theory of $\overline{B}(\mathcal{A})$ is the representation theory of the boundary: MC couplings are line defects.

Steinberg	Swiss-cheese
$\widetilde{\mathcal{N}} \rightarrow \mathcal{N}$ (resolution)	$\mathrm{FM}_k(X) \rightarrow \mathrm{Conf}_k(X)$ (compactification)
$\mathfrak{S} = \widetilde{\mathcal{N}} \times_{\mathcal{N}} \widetilde{\mathcal{N}}$ (self-intersection)	$\overline{B}(\mathcal{A}) \otimes_{\overline{B}(\mathcal{A}\text{-bimod})} \overline{B}(\mathcal{A})$ (Hochschild)
$H_*^{\mathrm{BM}}(\mathfrak{S})$ (Hecke algebra)	$\mathcal{Z}_{\mathrm{ch}}^{\mathrm{der}}(\mathcal{A})$ (derived center)
KL basis (from IC)	PBW basis (from spectral sequence)
Hecke modules	$\mathcal{A}^!$ -mod (line operators)
KL involution	Verdier/Koszul duality
Cell structure	Shadow depth classification (G/L/C/M)

The analogy would become an identification only after constructing a factorisation-homological comparison functor from the chiral configuration-space category to the Steinberg convolution category. In the present notes this functor is not constructed. The safe claim is the parallel of roles: Fulton–MacPherson compactification plays for chiral collision geometry a role analogous to the Springer resolution in Hecke theory, and the derived centre plays the role of a convolution endomorphism algebra.

The cell structure of the Hecke algebra (Kazhdan–Lusztig cells, Lusztig’s a -function, the asymptotic Hecke algebra) should have a shadow-tower analogue: the G/L/C/M classification of shadow depth is the analogue of the cell decomposition, with shadow depth playing the role of Lusztig’s a -function. Whether this analogy extends to a theorem is open.

19 What remains

Everything in §1–§18 can be said in two sentences.

The bar complex of a chiral algebra on a curve carries a differential (holomorphic direction) and a coproduct (topological direction); together these form a Swiss-cheese algebra on $\mathrm{FM}_k(\mathbb{C}) \times \mathrm{Conf}_k(\mathbb{R})$, presenting the boundary theory of a 3d holomorphic-topological QFT whose bulk is the chiral derived center, whose lines are modules for the Koszul dual, and whose modularity arises from trace and clutching on the open sector. For gravity, the coproduct is primitive (ghost-number obstruction from DS reduction), so all nonlinearity resides in the A_∞ products and the collision residue $r(z)$; for gauge theory, the coproduct is nontrivial, and the full two-channel structure is active.

That is what the 1-form told us when we gave it a second direction. What follows is what it does when you push it further: into the bordered moduli space, along the modular cooperad, past the death of the derived category at genus 1, through the spectral Drinfeld strictification, into the gravitational dichotomy at $c = 26$. Each direction is a computation that is either finished or honestly open.

*

The following structures are proved:

- (i) The Swiss-cheese operad $\mathrm{SC}^{\mathrm{ch}, \mathrm{top}}$ and its homotopy-Koszulity.
- (ii) The recognition theorem (Weiss cosheaf descent).

- (iii) PVA descent D1–D6 (exchange cylinder, Stokes).
- (iv) The four-stage open/closed architecture (Stages 1–3 proved; Stage 4 programme).
- (v) The bulk-boundary-line triangle (boundary-linear sector proved; global conjectural).
- (vi) Gravitational primitivity (principal DS; non-principal conjectural).
- (vii) The benchmark: $V_k(\mathfrak{sl}_2)$ on $(\mathbb{P}^1, \{0, \infty\})$, every component computed.
- (viii) The annulus trace $\simeq \mathrm{HH}_*(C_{\mathrm{op}})$.
- (ix) The completed modular Koszul datum $\Pi_X^{\mathrm{oc}}(\mathcal{A})$.

The following structures are open:

- (i) The full modular cooperad on the trace.
- (ii) The global bulk-boundary-line triangle outside the boundary-linear sector.
- (iii) BV/BRST = bar at genus $g \geq 1$.
- (iv) Non-principal gravitational primitivity beyond hook-type.
- (v) The spectral Drinfeld strictification for Kac–Moody algebras with root multiplicities > 1 .

*

A 1-form with a simple pole.

A relation among three.

A second direction: the coproduct.

The rest follows.

20 The composite graviton

The Virasoro stress tensor

$$T = \frac{1}{2(k + h^\vee)} \sum_a J^a J_a$$

is built from affine currents. It is not fundamental. The graviton is composite.

The ghost sector of the BRST complex remembers this: the coproduct is strictly primitive (Theorem 12.1; see the gauge/gravity comparison in §6).

In gauge theory, the cross-term survives because J^a is fundamental (ghost number 0, no passage through h):

$$\Delta_z(T_{\mathrm{aff}}) = \tau_z(T_{\mathrm{aff}}) \otimes 1 + 1 \otimes T_{\mathrm{aff}} + \frac{1}{k + h^\vee} \Omega(w+z, w).$$

The Casimir $\Omega = \sum_a J^a \otimes J_a$ is a production vertex. A gluon bound state dissociates into its constituents.

The r -matrix $r^{\mathrm{Vir}}(z) = (c/2)/z^3 + 2T/z$ carries all gravitational scattering. The cubic pole arises because the bar kernel $d \log(z - w)$ absorbs one power from the quartic OPE (see §32 for explicit pole orders).

21 The holographic triangle

Three vertices.

Boundary: $\mathcal{A}$ (the chiral algebra).

Bulk: $\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A}) = H^*(C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A}), \delta)$ (the chiral derived center).

Lines: $\mathcal{A}^!$ -modules (on the chirally Koszul locus).

*

The bar complex $\overline{B}(\mathcal{A})$ classifies couplings between boundary and lines. It is the universal twisting coalgebra: every map $\alpha: \overline{B}(\mathcal{A}) \rightarrow \mathcal{A}^!$ satisfying the twisting morphism equation is a line operator. On the Koszul locus:

$$\text{MC}(\text{Hom}(\overline{B}(\mathcal{A}), \mathcal{A}^!)) \simeq \text{Perf}(\mathcal{A}^!).$$

This is the bar complex's role: a representability theorem. It classifies morphisms, not operators.

The derived center $\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A})$ classifies bulk observables. It acts on the boundary via the brace dg-algebra structure on $C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A})$, encoding how bulk fields modify boundary correlators. The restriction $\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A}) \rightarrow \mathcal{A}$ is well-defined. The extension $\mathcal{A} \rightarrow \mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A})$ is not: bulk restricts to boundary, boundary does not determine bulk.

Warning 2I.I. $\overline{B}(\mathcal{A}) \neq \mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A})$. The bar complex is a Fourier kernel (Volume I). The derived center is a space of endomorphisms. One classifies morphisms; the other classifies operators. Their conflation is the most frequent source of false statements in three-dimensional holomorphic-topological field theory.

22 Where modularity lives

As in §8, modularity arises from trace and clutching on the open sector, not as an axiom on the closed algebra.

*

Cut S^1 into two arcs. Each arc is an interval $I \cong \mathbb{R}$. Excision on the factorisation homology of C_{op} :

$$\int_{S^1} C_{\text{op}} \simeq C_{\text{op}}(I_1) \otimes_{C_{\text{op}}(I_1 \cap I_2)}^{\mathbb{L}} C_{\text{op}}(I_2).$$

For a strongly admissible E_1 -chiral open sector, the two-arc cover produces the two-sided bar complex, hence the cyclic bar complex. Under this admissibility hypothesis Hochschild homology $\text{HH}_*(C_{\text{op}})$ is the annular trace object. When $\kappa \neq 0$ this trace is a curved annular object, not an ordinary flat invariant.

The first modular shadow: $\kappa(\mathcal{A})$ appears as the leading coefficient of the annulus trace. The genus-1 curvature $d_{\text{fib}}^2 = \kappa \cdot \omega_1$ is the obstruction to extending the genus-0 Swiss-cheese structure to the torus. The obstruction lives in the Hochschild homology of the open sector. It does not live in any axiom on the closed algebra.

Clutching: for $g \geq 2$, the closed genus- g surface Σ_g has a pants decomposition with $2g - 2$ pairs of pants and $3g - 3$ sewing circles. The categorical-trace construction often uses a different handle presentation: g self-clutchings from $2g$ punctures. These are distinct combinatorial models and should

not be identified. In the pants model each sewing circle contributes an HH_* factor, so the modular partition function is the trace over all sewings:

$$Z_g = \mathrm{Tr}_{\mathrm{HH}_*^{\otimes(3g-3)}}(\text{clutching maps}).$$

This is modularity from geometry, not from axioms.

23 The Koszul dual lives on the boundary

$D_{\mathrm{Ran}}(\overline{B}(\mathcal{A})) \simeq \overline{B}(\mathcal{A}^!)$: the Verdier dual of the bar coalgebra is the bar of the Koszul dual algebra $\mathcal{A}^!$ (Theorem A intertwining). The Koszul dual $\mathcal{A}^!$ lives on the $\mathbb{R}$ -direction (the boundary of the half-space $\mathbb{C}_{\geq 0} \times \mathbb{R}$), not in the $\mathbb{C} \times \mathbb{R}$ bulk.

*

For Chern–Simons with gauge group G at level k : $\mathcal{A} = V_k(\mathfrak{g})$, and the chiral Verdier dual is $\mathcal{A}_{\mathrm{ch}}^! = V_{-k-2h^\vee}(\mathfrak{g})$. The open line-side dual is $\mathcal{A}_{\mathrm{line}}^! = Y_h(\mathfrak{g})$. The Feigin–Frenkel involution $k \mapsto -k - 2h^\vee$ is Verdier duality on $\mathrm{Ran}(X)$. At the critical level $k = -h^\vee$: $V_{-h^\vee}(\mathfrak{g})$ is commutative, bar cohomology is functions on opers, and $\mathcal{A}^!$ at the dual critical level is the Feigin–Frenkel center.

For gravity: $\mathcal{A} = \mathrm{Vir}_c$, $\mathcal{A}^! = \mathrm{Vir}_{26-c}$.

At $c = 26$: $\mathcal{A}^! = \mathrm{Vir}_0$, uncurved ($\kappa = 0$).

At $c = 0$: $\mathcal{A} = \mathrm{Vir}_0$, uncurved.

At $c = 13$: $\mathcal{A} = \mathcal{A}^!$. Self-duality.

The complementarity sum:

$$\kappa(\mathrm{Vir}_c) + \kappa(\mathrm{Vir}_{26-c}) = \frac{c}{2} + \frac{26-c}{2} = 13 \neq 0.$$

For Kac–Moody algebras: $\kappa + \kappa^! = 0$ by Feigin–Frenkel (the involution $k \mapsto -k - 2h^\vee$ is anti-symmetric around 0). For Virasoro: the involution $c \mapsto 26 - c$ is anti-symmetric around 13, not around 0. The midpoint matters. It is 13, not 0.

24 The BTZ black hole from the r -matrix

The effective curvature of the matter-ghost system:

$$\kappa_{\mathrm{eff}} = \kappa(\mathrm{Vir}_c) + \kappa_{\mathrm{ghost}} = \frac{c}{2} - 13 = \frac{c - 26}{2}.$$

At $c = 26$: $\kappa_{\mathrm{eff}} = 0$. No curvature. The theory is topological.

At $c \neq 26$: the genus tower $F_g = \kappa_{\mathrm{eff}} \cdot \lambda_g^{\mathrm{FP}}$. The $\hat{A}$ -genus generates all F_g from κ_{eff} :

$$\sum_{g \geq 1} F_g \hbar^{2g} = \kappa_{\mathrm{eff}} (\hat{A}(i\hbar) - 1).$$

The Bernoulli numbers encode the higher-genus corrections. Each universal coefficient λ_g^{FP} is positive, while F_g has the uniform sign of κ_{eff} . Thus subcritical $c < 26$ gives negative genus coefficients in this normalization.

*

The collision residue $r^{\text{Vir}}(z) = (c/2)/z^3 + 2T/z$ supplies the Virasoro data that enter the Cardy/BTZ dictionary under the Brown–Henneaux hypotheses. The leading coefficient $c/2 = \kappa$ is the curvature scalar that enters the Cardy exponent; it is not itself the Bekenstein–Hawking entropy. The subleading $2T/z$ is state-dependent braiding; it distinguishes states within the same Virasoro theory.

The primitive coproduct is the algebraic analogue of a no-splitting statement. It does not by itself prove a statement about black-hole dynamics; it says that, in this chiral algebra, the only local channel is braiding. The production vertex $\Omega(w+z, w)$ of gauge theory (the Casimir cross-term) is absent.

	$c \neq 26$	$c = 26$
κ_{eff}	$(c - 26)/2 \neq 0$	0
F_1	$(c - 26)/48$	0
Genus tower	$\kappa_{\text{eff}} \cdot (\hat{A} - 1)$	collapsed
Regime	perturbative	topological

25 Five theories, one machine

	CS	Gravity	Twisted hol.	M2	M5
$\mathcal{A}$	$V_k(\mathfrak{g})$	Vir_c	$V_k(\mathfrak{g})$	DDCA $_K$	$\mathcal{W}_\infty(K)$
$\mathcal{A}_{\text{ch}}^!$	$V_{-k-2h^\vee}(\mathfrak{g})$	Vir_{26-c}	$V_{-k-2h^\vee}(\mathfrak{g})$	CE	?
κ	$\dim(\mathfrak{g}) \frac{k+h^\vee}{2h^\vee}$	$c/2$	$\dim(\mathfrak{g}) \frac{k+h^\vee}{2h^\vee}$	$K(K+1)/2$	$\ell_{\infty} c$
Class	L	M	L	L	M
Δ_z	nontrivial	primitive	nontrivial	nontrivial	primitive
$\kappa + \kappa^!$	0	13	0	0	ℓK_N

The machine does not know which theory it is computing. It receives: a chiral algebra, its OPE, and the bar construction. The five theories are five inputs to the same functor.

Chern–Simons and twisted holography are class L: the r -matrix carries all structure, the coproduct is nontrivial, the shadow tower terminates at arity 3. Gravity and M5 are class M: infinite shadow depth, primitive coproduct, $Q^{\text{ct}} \neq 0$.

*

The M2–M5 duality: the M2 algebra (DDCA, class L) and the M5 algebra ($\mathcal{W}_\infty$, class M) are related by the Miura transformation. DS reduction converts class L to class M. The reduction IS the depth increase. The ghost-number filtration that kills the coproduct of M5 is the same filtration that was absent for M2.

26 The four-stage architecture, revisited

Stage 1 (local one-colour): define the Swiss-cheese algebra. Prove the universal acting-bulk theorem $U(\mathcal{A}) = (C_{\text{ch}}^*(\mathcal{A}, \mathcal{A}), \mathcal{A})$. Everything succeeds or fails here.

Stage 2 (open primitive): the primitive object is C_{op} , not A_b . The boundary algebra $A_b = \text{End}(b)$ is a chart of a compact generator b in C_{op} . Different generators produce Morita-equivalent charts. The category is the invariant.

Stage 3 (globalise): move from $\mathbb{C} \times \mathbb{R}$ to tangential log curves (X, D, τ) . The real oriented blowup $\pi: \tilde{X}_D \rightarrow X$ replaces each puncture p_i by a circle $S_{p_i}^1$; the tangential basepoint τ_{p_i} cuts this circle into an interval $I_{p_i} \cong \mathbb{R}$. Open insertions live on the interval. Bulk insertions live in the interior. The global theory is a factorisation algebra on a bordered Riemann surface.

Stage 4 (modularise): introduce Θ^{oc} , traces, annulus/Hochschild chains, clutching, quartic resonance classes. Only after stages 1–3 are solid.

*

Each stage depends on its predecessor. Discussion of stage k before establishment of stage $k - 1$ is not premature; it is wrong.

27 What the bar complex knows about quantum gravity

The bar complex $\overline{B}(\text{Vir}_c)$ is a factorisation coalgebra on $\text{Ran}(X)$. Its differential $d_{\overline{B}}$ extracts collision residues of the Virasoro OPE. Its coproduct Δ deconcatenates ordered tuples along $\mathbb{R}$.

At genus 0: $d_{\overline{B}}^2 = 0$ by Arnold. The bar complex is an honest chain complex. Its cohomology has dimensions

$$1, 2, 5, 12, 30, 76, 196, 512, 1353, \dots$$

The generating function satisfies $x^3 P^2 - (1 - 2x)(1 - x^2)P + (1 - x)(1 - x^2) = 0$. Discriminant: $(1 - x)^2(1 - 3x)(1 + x)$. Growth rate 3.

*

At genus 1: $d_{\text{fib}}^2 = (c/2) \cdot \omega_1 \neq 0$. The bar complex is curved. The curvature $c/2$ is the modular characteristic.

At genus g :

$$F_g = \frac{c}{2} \cdot \lambda_g^{\text{FP}} = \frac{c}{2} \cdot \frac{(2^{2g-1} - 1) |B_{2g}|}{(2g)! \cdot 2^{2g-1}}.$$

The Bernoulli numbers. The $\hat{A}$ -genus. From index theory. Nothing in the Virasoro OPE predicts this. It lives in the geometry of $\overline{\mathcal{M}}_g$.

*

The shadow obstruction tower

$$\begin{aligned} S_2 &= c/2, \\ S_3 &= 2, \\ S_4 &= 10/[c(5c + 22)], \\ S_5 &= -48/[c^2(5c + 22)], \end{aligned}$$

and all higher S_r , are the Taylor coefficients of $\sqrt{Q}$ where

$$Q_{\text{Vir}}(t) = c^2 + 12ct + \frac{180c + 872}{5c + 22} t^2.$$

One quadratic. One square root. An algebraic function of degree 2.

Three numbers determine the entire infinite tower of higher-genus corrections to quantum gravity: $\kappa = c/2$, $\alpha = 2$ (the cubic shadow), and $S_4 = 10/[c(5c + 22)]$ (the quartic contact invariant). The shadow metric Q is constructed from these three. The contact square-class

$$\Delta_{\text{ct}} := 8\kappa S_4 = \frac{40}{5c + 22}$$

controls the convergence radius of the shadow obstruction tower. It is not the polynomial discriminant of Q_{Vir} . When $\Delta_{\text{ct}} \neq 0$ (all $c \neq 0$): the tower is infinite, class M. The bar complex knows the exact answer at every genus, as the coefficients of an algebraic function.

28 The arithmetic structure of quantum gravity

The gravitational shadow obstruction tower is the arithmetic of the quadratic extension $K = \mathbb{Q}(c)(t)(\sqrt{Q_{\text{Vir}}})$ over the function field $F = \mathbb{Q}(c)(t)$. The shadow metric

$$Q_{\text{Vir}}(t) = c^2 + 12ct + \frac{180c + 872}{5c + 22} t^2$$

is a quadratic polynomial whose square root generates the infinite tower of higher-genus corrections to three-dimensional quantum gravity.

*

The discriminant. $\text{disc}(Q_{\text{Vir}}) = -320 c^2 / (5c + 22)$. Negative for all $c > 0$: the roots of Q_{Vir} are complex conjugate, the extension K/F is genuine, and the shadow obstruction tower is infinite (class M).

The actual discriminant and the contact square-class control three quantities at once:

- (i) The depth of the gravitational perturbation series (infinite for all $c \neq 0$, because $\Delta_{\text{ct}} = 40/(5c + 22) \neq 0$).
- (ii) The convergence radius of the shadow obstruction tower: the growth rate $\rho = \sqrt{36 + 80/(5c + 22)} / c$ is the reciprocal of the distance from the origin to the nearest branch point of $\sqrt{Q_{\text{Vir}}}$.
- (iii) The complementarity with the dual theory at $c' = 26 - c$: $\Delta_{\text{ct}}(c) + \Delta_{\text{ct}}(26 - c) = 6960/[(5c + 22)(152 - 5c)]$, with universal numerator.

*

The gravitational number field. The chiral Cardy contribution $2\pi\sqrt{c\Delta/6}$, with $\Delta = L_0 - c/24$, derives from $\kappa = c/2$, the leading coefficient of Q_{Vir} . This coefficient is the constant term (up to a square): $Q_{\text{Vir}}(0) = c^2 = 4\kappa^2$. The leading OPE datum seeds the quadratic extension.

The growth rate ρ measures how fast the higher-genus corrections to the gravitational partition function grow. When $\rho < 1$, the shadow obstruction tower converges: the shadow partition function $Z^{\text{sh}} = \sum Z_g^{\text{sh}} \hbar^{2g}$ exists as a convergent series. This convergence is an analytic property of the shadow series at central charge c . It should not be identified with splitting of a prime in the associated quadratic field without an additional arithmetic construction.

Setting $\rho = 1$ yields the critical cubic $5c^3 + 22c^2 - 180c - 872 = 0$ with positive root $c^* \approx 6.125$. For $c > c^*$: the shadow obstruction tower converges ($\rho < 1$, the gravitational perturbation series sums). For $0 < c < c^*$: the shadow obstruction tower diverges ($\rho > 1$, the perturbation series requires resummation). The critical cubic is the analytic boundary of the gravitational shadow curve: it separates the convergent regime from the divergent regime. Any relation with Minkowski bounds in a number field is conjectural and is not used here.

*

The three critical values.

c	What happens	Arithmetic meaning
0	$\kappa = 0$, Q degenerates	ramified prime (shadow obstruction tower is undefined)
13	$\mathcal{A} = \mathcal{A}^\dagger$, self-dual	Galois involution is trivial on coefficients; $K = K'$
26	$\kappa_{\text{eff}} = 0$, topological	dual extension K' degenerates ($\kappa' = 0$)

At $c = 0$: the constant term of Q_{Vir} vanishes. The quadratic polynomial has a double root at $t = 0$. The shadow connection ∇^{sh} has an irregular singularity. The extension ramifies.

At $c = 13$: the theory is self-dual ($\text{Vir}_{13}^\dagger = \text{Vir}_{13}$). The Koszul involution $c \mapsto 26 - c$ fixes $c = 13$. The two quadratic extensions K and K' coincide. The complementarity sum $\kappa + \kappa' = 13$ does not vanish: self-duality is a symmetry enhancement, not anomaly cancellation. The growth rate $\rho(13) \approx 0.467$: the shadow obstruction tower converges at the self-dual point.

At $c = 26$: the effective curvature $\kappa_{\text{eff}} = (c-26)/2 = 0$ vanishes. The dual algebra Vir_0 has $\kappa' = 0$: its shadow extension ramifies. The scalar effective genus lane becomes topological. The Clifford algebra degenerates from a matrix algebra (2^g -dimensional) to an exterior algebra (2^{2g} -dimensional). This does not by itself imply that the full BTZ partition function collapses; the non-scalar contact and shadow data must be treated separately.

These three values are not phases of one theory. They are three qualitatively distinct points in the arithmetic landscape of the quadratic extension: a ramified prime ($c = 0$), a self-dual fixed point ($c = 13$), and a degeneration of the dual ($c = 26$). They are separated by 13 units of central charge.

*

The ramified primes. The denominator theorem (Volume I) gives $\text{denom}(S_r) = (\text{const}) \cdot c^{r-3}(\zeta c+22)^{\lfloor (r-2)/2 \rfloor}$. Two primes ramify:

- (i) $c = 0$: the leading OPE coefficient vanishes. No Bekenstein–Hawking entropy. No bar curvature. The shadow metric $Q(0, t) = 872 t^2 / (5 \cdot 22) = 872 t^2 / 110$ degenerates.
- (ii) $c = -22/5$: the weight-4 Gram determinant $\det G_4 = c^2(\zeta c+22)/2$ vanishes. A null vector at weight 4 collapses the quasi-primary Λ onto $\partial^2 T$. The quartic contact invariant $Q^{\text{ct}} = 10/[c(\zeta c+22)]$ has a pole.

Every other value of c is unramified: the shadow coefficients are finite, the quadratic extension is well-defined, and the tower runs.

No higher Kac determinant appears. The gravitational number field has exactly two ramified primes, both visible from the weight-4 representation theory. The infinite tower of higher-genus gravitational corrections is controlled by a single 2×2 Gram matrix.

*

The analytic radius parameter. The growth rate $\rho = \sqrt{36 + 80/(\zeta c+22)} / c$ is the analytic radius parameter for the shadow obstruction tower. It should not be identified with a fundamental unit without a separate number-theoretic theorem. It controls convergence of the shadow series:

- $\rho < 1$ ($c > c^*$): the shadow obstruction tower converges. The gravitational path integral exists non-perturbatively as a convergent shadow series. The shadow partition function Z^{sh} is the value of a convergent double series (genus and arity).
- $\rho > 1$ ($0 < c < c^*$): the shadow obstruction tower diverges. The shadow coefficients grow exponentially. Resummation (Borel transform of $\sqrt{Q_{\text{Vir}}}$) is required. The Stokes constants of the shadow obstruction tower are the non-perturbative content.
- $\rho = 1$ ($c = c^*$): the critical cubic. The branch point of $\sqrt{Q_{\text{Vir}}}$ lies exactly on the unit circle. The shadow obstruction tower is marginally divergent.

c	ρ	Regime
1	2.99	divergent (shadow)
$c^* \approx 6.125$	1.00	critical
13	0.467	convergent
26	0.234	convergent (dual topological)
100	0.061	strongly convergent

The string partition function Z_{string} (genus factorial growth $(2g)!$) always diverges. The shadow partition function Z^{sh} (Bernoulli decay $1/(2\pi)^{2g}$ times shadow growth $\rho^r r^{-5/2}$) converges for $c > c^*$. The shadow obstruction tower is better-behaved than the string because it sums over arities within a fixed genus, while the string sums over genera with unrestricted growth.

*

The Galois involution. The monodromy -1 of the shadow connection $\nabla^{\text{sh}} = d - Q'/2Q dt$ around each branch point of $\sqrt{Q_{\text{Vir}}}$ is the nontrivial element of $\text{Gal}(K/F)$. In the gravitational context: the

Koszul sign is the Galois involution of the number field. The sign alternation in the shadow obstruction tower S_r (positive for even r , approximately negative for odd r , with beat period $\pi/(\pi - \theta)$ where $\theta = \arg(t_+)$) is the manifestation of the Galois action on the Taylor coefficients of $\sqrt{Q_{\text{Vir}}}$.

This is the deepest structural content of the bar construction's desuspension: the sign $(-1)^n$ at bar degree n is the Galois automorphism of a quadratic extension, evaluated at the n -th coefficient.

*

The gravitational shadow obstruction tower is not like a quadratic extension. It is one, over the function field $\mathbb{Q}(c)(t)$ instead of $\mathbb{Q}$. The Cardy/Brown–Henneaux entropy reads the leading asymptotic coefficient after the physical dictionary is imposed. The convergence of the perturbation series is the analytic boundary of this quadratic extension; arithmetic splitting requires an additional construction. The Koszul sign is the Galois involution. The critical cubic is the analytic boundary of the shadow series. The two ramified parameters are the Kac determinant zeros. The complementarity identity is a duality constraint on discriminants. Arithmetic interpretations beyond this analytic statement are conjectural.

A 1-form with a simple pole.

A relation among three.

A second direction: the coproduct.

A quadratic extension: the shadow.

The rest follows.

29 Gravity at rational central charge

The generic gravitational number field $K = \mathbb{Q}(c)(t)(\sqrt{Q_{\text{Vir}}})$ of the preceding section lives over the function field $\mathbb{Q}(c)$. When the central charge specialises to a rational number c_0 , the field specialises to a concrete quadratic extension of $\mathbb{Q}$.

For a minimal model $c_{p,q} = 1 - 6(p - q)^2/(pq)$, the contact square-class $\Delta_{\text{ct}}(c_{p,q}) = 40/(5c_{p,q} + 22)$ is a specific rational number, and $K_{\text{ct}}(c_{p,q}) := \mathbb{Q}(\sqrt{\Delta_{\text{ct}}(c_{p,q})})$ is a specific real quadratic contact field. The actual branch field of $\sqrt{Q_{\text{Vir}}}$ has square-class $-2\Delta_{\text{ct}}$.

*

The physical picture. The curvature scalar $\kappa = c/2$ at a rational central charge $c_{p,q}$ is a rational number; the Bekenstein–Hawking entropy is obtained only after the Brown–Henneaux/Cardy asymptotic step. The higher-genus corrections $F_g = \kappa \cdot \lambda_g^{\text{FP}}$ are rational multiples of κ , hence rational. The perturbative gravitational partition function $\sum F_g \hbar^{2g}$ has rational coefficients.

But the shadow obstruction tower is different. The Taylor coefficients S_r of $\sqrt{Q_L}$ are rational (they satisfy a rational recursion), yet the generating function $H(t) = t^2 \sqrt{Q_L(t)}$ is algebraic and genuinely quadratic away from the rational-square locus for $\Delta_{\text{ct}}(c)$. For the listed minimal-model examples below the squarefree part is nontrivial. The arithmetic content of the shadow obstruction tower is visible in this quadratic branch structure, not in any finite truncation of the perturbative expansion.

This is not a deficiency of perturbation theory. The function $H(t)$ is algebraic of degree 2; its Taylor coefficients are all individually rational. The irrationality is non-perturbative in the arity variable t , not in the genus variable $\hbar$. It is visible in the branch structure of $\sqrt{Q_L}$, not in any single coefficient.

*

Computation. Write $5c_0 + 22 = a/b$ in lowest terms. Then $\Delta_{\text{ct}}(c_0) = 40b/a$, and the specialised contact field is $K_{\text{ct}}(c_0) = \mathbb{Q}(\sqrt{\text{sqfree}(40ab)})$. The branch field is $K_{\text{br}}(c_0) = \mathbb{Q}(\sqrt{-2\Delta_{\text{ct}}(c_0)})$.

$c = 1/2$ (*Ising model*). $5c + 22 = 49/2$. $\Delta_{\text{ct}} = 80/49$. $\sqrt{80/49} = 4\sqrt{5}/7$. The Ising contact field is $\mathbb{Q}(\sqrt{5})$; the branch field is $\mathbb{Q}(\sqrt{-10})$.

The golden ratio $(1 + \sqrt{5})/2$ is the fundamental unit of this field, with norm -1 . The class number is $h = 1$: the ring of integers $\mathbb{Z}[(1 + \sqrt{5})/2]$ is a principal ideal domain. The Ising model produces the simplest possible arithmetic. One is tempted to say that the Ising model is “arithmetically trivial,” as it is physically the simplest unitary minimal model.

The shadow growth rate is $\rho(1/2) \approx 12.53$; the shadow obstruction tower diverges violently ($c = 1/2$ is far below the critical cubic $c^* \approx 6.125$). The Ising gravity requires resummation.

$c = 7/10$ (*tricritical Ising*). $5c + 22 = 51/2$. $\Delta_{\text{ct}} = 80/51$. $K_{\text{ct}}(7/10) = \mathbb{Q}(\sqrt{255})$ where $255 = 3 \cdot 5 \cdot 17$. The branch field is $\mathbb{Q}(\sqrt{-510})$. Discriminant 1020. Class number $h = 4$: a genuine failure of unique factorisation.

$c = 4/5$ (*three-state Potts*). $K_{\text{ct}}(4/5) = \mathbb{Q}(\sqrt{65})$. Discriminant 65. $h = 2$. The branch field is $\mathbb{Q}(\sqrt{-130})$. The Potts-model gravity has a non-trivial ideal class group $\text{Cl}(K) \cong \mathbb{Z}/2$.

$c = 13$ (*self-dual*). $K_{\text{ct}}(13) = \mathbb{Q}(\sqrt{870})$ where $870 = 2 \cdot 3 \cdot 5 \cdot 29$. The branch field is $\mathbb{Q}(\sqrt{-435})$. Discriminant 3480. $h = 8$.

The self-dual gravity has the largest class number of any integer central charge in $[0, 26]$. It sees the prime 29, inherited from the complementarity constant $6960 = 2^4 \cdot 3 \cdot 5 \cdot 29$. No other central charge in the standard range detects this prime.

$c = 26$ (*critical string*). $K_{\text{ct}}(26) = \mathbb{Q}(\sqrt{95})$. Discriminant 380. $h = 2$. The branch field is $\mathbb{Q}(\sqrt{-190})$. $\rho(26) \approx 0.232$: convergent. This is the gravitational number field of the bosonic string at the critical dimension.

c	$\Delta_{\text{ct}}(c)$	$d(c)$	disc	h	ε	$\rho(c)$
1/2	80/49	5	5	1	$(1+\sqrt{5})/2$	12.53
7/10	80/51	255	1020	4	$16+\sqrt{255}$	8.94
4/5	20/13	65	65	2	$8+\sqrt{65}$	7.81
1	40/27	30	120	2	$11+2\sqrt{30}$	6.24
13	40/87	870	3480	8	$59+2\sqrt{870}$	0.47
25	40/147	30	120	2	$11+2\sqrt{30}$	0.24
26	5/19	95	380	2	$39+4\sqrt{95}$	0.23

*

Koszul duality and the field pair. The Koszul pair $(c, 26 - c)$ produces two fields $K(c)$ and $K(26 - c)$. These coincide iff $(5c + 22)/(152 - 5c) \in \mathbb{Q}^{\times 2}$.

At $c = 1$ and $c = 25$: the ratios are reciprocal squares; for $c = 25$ one has $147/27 = (7/3)^2$. Both give $\mathbb{Q}(\sqrt{30})$.

At $c = 13$: the ratio is $87/87 = 1$. Self-duality forces field-preservation.

For the Ising model: the ratio is $49/299 = 49/(13 \cdot 23)$, which is not a perfect square. The Ising gravity at $c = 1/2$ lives over $\mathbb{Q}(\sqrt{5})$; its Koszul dual at $c = 51/2$ lives over $\mathbb{Q}(\sqrt{1495})$ where $1495 = 5 \cdot 13 \cdot 23$. Different fields, different class numbers, different arithmetic. Koszul duality does not preserve the gravitational number field at the Ising point.

This failure is generic. Among all minimal models $\mathcal{M}(p, q)$ with $p < 10$, none has the Koszul pair giving the same field. The criterion $(5c + 22)/(152 - 5c) \in \mathbb{Q}^{\times 2}$ requires an arithmetic coincidence that the minimal model spectrum does not provide.

*

What the class number measures. The class number h of $K(c)$ is a measure of the arithmetic complexity of gravity at central charge c . In algebraic number theory, h counts the failure of unique factorisation in the ring of integers $\mathcal{O}_K$.

In the gravitational context: $h = 1$ means the shadow obstruction tower's arithmetic is "principal," governed by a single generator. $h > 1$ means the shadow arithmetic requires multiple ideal classes. Whether this has a direct physical interpretation (a counting of distinct gravitational saddle classes) is not known.

c	h	Interpretation
$1/2$ (Ising)	1	principal: simplest arithmetic
$4/5$ (Potts)	2	one non-trivial ideal class
$7/10$ (tricrit.)	4	four ideal classes
13 (self-dual)	8	most complex in standard range

*

What fails. The growth rate $\rho(c)$ is a smooth algebraic function of c . The fundamental unit $\varepsilon(d(c))$ of $K(c)$ depends on c through the squarefree part $d(c)$, which is a wildly discontinuous function of the central charge. No algebraic relation connects ρ and ε .

A conjecture that the fundamental unit of the gravitational number field controls the shadow growth rate was tested by computing both quantities at $c = 1/2, 7/10, 4/5, 1, 13, 25, 26$ and found to be false. At $c = 1/2$: $\rho \approx 12.53$ while $\varepsilon = (1 + \sqrt{5})/2 \approx 1.618$. At $c = 13$: $\rho \approx 0.467$ while $\varepsilon = 59 + 2\sqrt{870} \approx 117.99$. The two quantities vary in opposite directions.

The failure is structural: $\rho(c)$ is a smooth function of c , while $\varepsilon(d(c))$ is a step function. A smooth function cannot equal a step function.

*

What remains. The specialisation $c \mapsto K(c)$ is a new functor from (a subset of) the rational points of the Virasoro central charge line to the set of real quadratic number fields. It sends the OPE data at genus 0 (the stress tensor and its weight-4 descendant) to a number field whose arithmetic is entirely determined by the bar complex.

The family $\{K(c_{p,q})\}_{(p,q)}$ attached to the minimal model tower constitutes a new arithmetic invariant of 2d CFT. Whether this family has structure beyond what is visible in the table above is an open question.

The first instance of the specialisation functor applied to gravity is the Ising model. The shadow obstruction tower of the Ising model lives over $\mathbb{Q}(\sqrt{5})$, the field of the golden ratio. This is the number field with class number 1 and the smallest possible discriminant among real quadratic fields with fundamental unit of norm -1 . The simplest unitary minimal model produces the simplest real quadratic field.

Whether this simplicity persists along the minimal model tower, or whether more complex arithmetic emerges, is a question at the intersection of vertex algebra theory and algebraic number theory that the bar construction makes precise.

The bar complex is a 1-form.

Its square root is a number field.

Gravity at rational central charge is arithmetic.

30 Fourier duality from operads to L -functions

The bar construction is a Fourier transform (§??, Volume I). The shadow obstruction tower is a quadratic extension (§28). The Dirichlet-sewing lift $S_{\mathcal{A}}(u)$ is a product of zeta functions (§??, Volume I). These three objects arise from the same chiral algebra. This section asks: do they form a “descent chain” in which a single Fourier duality descends from operadic algebra to analytic number theory?

The answer is: partially. The chain has five levels and three distinct involutions. The first two links are theorems. The third is broken. The fourth is lattice-specific. The claim “they are the same involution” is false.

30.1 The three involutions

The physical content of the bar construction is that it extracts the OPE residues of a chiral algebra into a nilpotent differential, converting the multiplicative structure (operator product) into an additive structure (differential). This extraction carries three symmetries:

- (i) **Verdier duality** $\mathbb{D}_{\text{Ran}}$ on $\text{Ran}(X)$. Exchanges $\overline{B}(\mathcal{A})$ and $\overline{B}(\mathcal{A}^!)$ (Theorem A, Volume I). This is the Fourier involution: it intertwines convolution with pointwise operations on factorisation (co)algebras. Its kernel is $\eta_{ij} = d \log(z_i - z_j)$.
Fixed locus: self-dual factorisation coalgebras.
- (ii) **Galois involution** σ of the shadow extension $K_L = \mathbb{Q}(c)(t)(\sqrt{Q_L})$. Sends $\sqrt{Q_L} \mapsto -\sqrt{Q_L}$. This is the monodromy of the shadow connection ∇^{sh} : transport around a branch point of $\sqrt{Q_L}$ returns $-\sqrt{Q_L}$. It is the Koszul sign $(-1)^n$ at bar degree n .
Fixed locus: the base field $F = \mathbb{Q}(c)(t)$.

- (iii) **Koszul involution** $\mathcal{A} \mapsto \mathcal{A}^!$ on families of chiral algebras. For Virasoro: $c \mapsto 26 - c$. For Kac–Moody: $k \mapsto -k - 2h^\vee$. This acts on the *coefficients* of the shadow metric Q_L , not on $\sqrt{Q_L}$ itself.

Fixed locus: self-dual algebras ($c = 13$ for Virasoro).

These three involutions are related but distinct. Verdier duality produces the Koszul involution as its shadow on moduli: $\mathbb{D}_{\text{Ran}}(\overline{B}(\mathcal{A})) \simeq \overline{B}(\mathcal{A}^!)$ implies that $\mathcal{A} \mapsto \mathcal{A}^!$ is the trace of Verdier duality on isomorphism classes. The Galois involution is intrinsic to a *single* algebra’s shadow obstruction tower and has no direct relation to Verdier duality. It arises because the MC equation $D\Theta + \frac{1}{2}[\Theta, \Theta] = 0$, projected to the scalar arity line, reduces to a Riccati equation whose solution $H(t) = t^2 \sqrt{Q_L}$ is algebraic of degree 2—not higher, because the Riccati is quadratic.

The claim “they are the same involution (Fourier) acting at different levels” conflates (i)–(iii). The correct statement: they are three $\mathbb{Z}/2$ -actions on three different categories, all originating from the bar construction but not related by any “descent.” At the self-dual point $c = 13$, all three have compatible fixed-point behaviour (the Koszul pair coincides, the shadow extensions K_L and $K_{L!}$ agree, and the Verdier dual coalgebra is isomorphic to the original). At generic c , they diverge: the Galois involution of K_L has nothing to do with the Koszul involution on the c -line.

30.2 Where the chain breaks

The descent chain has five levels:

Level	Object	Status
0	Koszul duality $\mathcal{A} \mapsto \mathcal{A}^!$	Proved (Theorem A)
1	Bar as Fourier: $\overline{B}_X$, inversion, Plancherel	Proved (Theorems A,B,C)
2	Shadow obstruction tower as quadratic extension	Proved
3	Dirichlet-sewing lift $S_{\mathcal{A}}(u)$	Defined, but independent of Level 2
4	Zeros of ε_s^c on critical lines	Lattice only; structural obstruction

The break occurs between Levels 2 and 3. The shadow obstruction tower is determined by (κ, α, S_4) —the arity-2, 3, 4 OPE data—and lives over $\mathbb{Q}(c)(t)$. The Dirichlet-sewing lift is determined by the weight multiset $\mathcal{W}(\mathcal{A}) = \{w_i\}$ and lives over the complex u -plane. These are independent invariants: two algebras with the same weight multiset but different OPE structure constants have the same $S_{\mathcal{A}}(u)$ but different shadow obstruction towers. Conversely, two algebras with the same (κ, α, S_4) but different weight multiplicities have the same shadow obstruction tower but different $S_{\mathcal{A}}(u)$.

30.3 The structural obstruction

For lattice VOAs, the constrained Epstein zeta ε_s^c factors into L -functions because the theta function Θ_Λ decomposes under the Hecke algebra into Eisenstein series and eigenforms. This decomposition uses three properties special to the lattice setting: the theta function is a classical modular form, the Hecke decomposition is a finite sum, and the Fourier coefficients are lattice representation numbers with multiplicative structure.

None of these holds for the Virasoro algebra. The Virasoro character $q^{-c/24} \prod (1 - q^n)^{-1}$ is not a modular form of finite weight. The shadow obstruction tower still runs (class M, infinite depth), but the arithmetic sieve does not apply. The MC equation constrains the spectral coefficients on the *real* spectral axis; the zeta zeros live at *complex* spectral parameters. This separation is structural (Remark ??,

Volume I): algebraic constraints on the spectral line cannot reach the scattering poles without analytic continuation of the spectral data off the real axis.

Concretely: the modified Li coefficients $\tilde{\lambda}_n(\mathcal{H})$ for the Heisenberg sewing lift $S_{\mathcal{H}}(u) = \zeta(u)\zeta(u+1)$ are positive for $n = 1, \dots, 6$ and **negative at $n = 7$** (compute/tests/test_euler_koszul_engine.py, line 394). Positivity of all Li coefficients would be equivalent to GRH for $\zeta(u)\zeta(u+1)$. The sign change at $n = 7$ shows that the sewing-lift Li coefficients do not satisfy a “shadow RH.” (This does not contradict RH for ζ alone; the sign change is an artefact of the product and the regularisation.)

30.4 What the bar construction does provide

The descent chain, as a linear sequence, is broken. But the bar construction does provide something more interesting: a *fan* of three independent projections from a single MC element.

Projection	Output	Content
Genus tower	$F_g = \kappa \cdot \lambda_g^{\text{FP}}$	Topological (Mumford classes)
Shadow obstruction tower	$\{S_r\}_{r \geq 2} = [t^{r-2}] \sqrt{Q_L}$	Arithmetic (quadratic extension, discriminant)
Koszul dual	$\mathcal{A}^\dagger = (\overline{B}(\mathcal{A}))^\vee$	Algebraic (Verdier dual)

These three projections are facets of $\Theta_{\mathcal{A}} \in \text{MC}(\mathfrak{g}_{\mathcal{A}}^{\text{mod}})$, the universal MC element in the modular cyclic deformation complex. The genus tower is the scalar projection of $\Theta_{\mathcal{A}}$ to each genus. The shadow tower is the arity projection of $\Theta_{\mathcal{A}}$ on the primary line. The Koszul dual is the genus-0, arity-2 projection (the binary pairing that determines $\mathcal{A}^\dagger$).

In the gravitational context ($\mathcal{A} = \text{Vir}_c$):

- The genus tower gives $F_g = (c/2)\lambda_g^{\text{FP}}$: the Bernoulli numbers. Higher-genus gravitational partition functions.
- The shadow obstruction tower gives $\sqrt{Q_{\text{Vir}}}$: the quadratic extension $K = \mathbb{Q}(c)(t)(\sqrt{Q})$ with discriminant $-320c^2/(5c+22)$. The arithmetic of quantum gravity.
- The Koszul dual gives Vir_{26-c} : the dual gravitational theory. $c + c' = 26$ is Freudenthal–de Vries.

All three are proved. All three are outputs of the single object Θ_{Vir} . But they are three outputs, not five levels of one chain.

30.5 The correct picture

The bar construction is a Fourier transform. This is a theorem, not a metaphor (Volume I, Theorems A, B, C). The shadow obstruction tower is a quadratic extension. This is a theorem, not an analogy (§28). But the claim that these two facts are levels of a “descent chain” that continues to L -functions and the Riemann hypothesis is false.

The reason it is false is not a failure of imagination; it is a theorem. The structural obstruction (Remark ??) shows that algebraic constraints from the MC equation act on the real spectral line, while the zeta zeros live at complex spectral parameters. No amount of clever identification can bridge this gap: it is the difference between a finite-dimensional algebraic structure (the shadow obstruction tower, determined by three numbers κ, α, S_4) and an infinite-dimensional analytic object (the zeta function, with infinitely many independent zeros).

The shadow obstruction tower *detects* arithmetic—Hecke eigenforms for lattice VOAs, quadratic fields for all VOAs at rational c —but it does not *control* the arithmetic. The detection is a theorem

(Theorem ??). The control would require a mechanism for the MC equation to force zeros onto critical lines, and no such mechanism exists.

What remains is beautiful and proved. The bar construction of a chiral algebra is a Fourier transform that simultaneously produces topological invariants (Mumford classes), arithmetic invariants (quadratic fields), and algebraic invariants (Koszul duals) from a single MC element. The gravitational shadow obstruction tower, specialised to rational central charge, assigns a number field to each minimal model. The Ising model lives over $\mathbb{Q}(\sqrt{5})$. The self-dual gravity at $c = 13$ lives over $\mathbb{Q}(\sqrt{870})$. Whether these number fields have structure beyond what is visible in the specialisation table is an open question at the intersection of vertex algebra theory and algebraic number theory.

The bar construction makes the question precise. It does not answer it.

30.6 The four Dirichlet series and the Benjamin–Chang resolution

The preceding subsections demonstrate that the descent chain is broken. But the *reason* it is broken encodes a positive insight about the arithmetic programme that deserves explicit articulation.

Four distinct Dirichlet series. The monograph constructs (or encounters) four Dirichlet series from a chirally Koszul algebra $\mathcal{A}$:

	Object	Input	Where it lives
(a)	Shadow-metric Epstein $\varepsilon_{Q_L}(s)$	(κ, α, Δ)	Arity axis, genus 0
(b)	Constrained Epstein ε_s^c	Primary spectrum $\{(\Delta_i, d_i)\}$	Genus axis, genus 1
(c)	Shadow Dirichlet $\zeta_{\mathcal{A}}(s)$	Shadow tower $\{S_r\}$	Arity axis, genus 0
(d)	Categorical zeta $\zeta_{\mathfrak{g}}^{\text{DK}}(s)$	$\{\dim V_\lambda\}$	Lie-theoretic, no genus

Plus the Dirichlet-sewing lift $S_{\mathcal{A}}(u) = \zeta(u+1) \sum_i (\zeta(u) - H_{w_i-1}(u))$, determined by the weight multiset $W(\mathcal{A})$ —a fifth object, independent of the above four.

The “negative results” of the preceding subsections (shadow zeta not in Selberg class, no Euler product, no s -reflection functional equation) concern objects (a) and (c): the arity-axis Dirichlet series. Benjamin–Chang [BenjaminChang22] proved that the Riemann zeta zeros control asymptotic scaling of operators through object (b): the constrained Epstein zeta. These are *different objects living on orthogonal axes* of the bigraded shadow algebra $\mathcal{A}_{r,g}^{\text{sh}}$.

Where the Riemann zeta enters. The Riemann zeta zeros ρ_n appear through two distinct mechanisms, both on the genus side:

- (i) *Benjamin–Chang spectral decomposition.* The scattering factor $F_c(s) = \zeta(2s)/\zeta(2s-1)$ in the Eisenstein spectral decomposition of $\hat{Z}^c = y^{c/2} |\eta|^{2c} Z$ on $\text{SL}(2, \mathbb{Z}) \backslash \mathfrak{H}$ has poles at $s = (1 + \rho_n)/2$. The pole *locations* are universal (from $\zeta(2s-1) = 0$); the pole *residues* are CFT-specific (primary multiplicities integrated against Eisenstein residues). This is the spectral theory of $\mathcal{M}_{1,1}$.
- (ii) *Dirichlet-sewing lift.* For Heisenberg, $S_{\mathcal{H}}(u) = \zeta(u)\zeta(u+1)$: the Riemann zeta enters through the weight multiset (the sewing sum $\sum_{n=1}^{\infty} n^{-u}$ over all integer modes of a weight-1 field). For Virasoro, $S_{\text{Vir}}(u) = \zeta(u+1)(\zeta(u) - 1)$: the ζ -factor persists but the Euler product breaks.

The Riemann zeta does *not* enter through the shadow obstruction tower. The shadow Dirichlet series (c) is entire, has exponentially decaying coefficients, is not in the Selberg class, and has no Euler product. These are not “negative results about the Benjamin–Chang programme”—they are positive

structural theorems about the arity axis, which operates by different principles (MC recursion, Koszul complementarity) than the genus axis (Euler product, functional equation).

The arity–genus orthogonality principle. In the bigraded MC element $\Theta_{\mathcal{A}} \in \mathcal{A}_{r,g}^{\text{sh}}$: the shadow obstruction tower is the $(r, 0)$ slice, the genus tower is the $(0, g)$ slice, and the constrained Epstein is extracted from $(0, 1)$ by Rankin–Selberg. The two axes interact only through:

- The MC equation, which couples (r_1, g_1) to (r_2, g_2) via the planted-forest corrections (the shadow visibility genus: $g_{\min}(S_r) = \lfloor r/2 \rfloor + 1$, Vol I, Corollary ??).
- The genus-2 non-diagonality: at genus ≥ 2 , the off-diagonal sewing blocks R_{ij} couple the handle structure to the inter-handle OPE, breaking the genus-1 factorisation barrier.

The descent chain breaks at Level $2 \rightarrow 3$ because it attempts to descend along the arity axis to a target (zeros of ε_s^c) that lives on the genus axis. The correct picture is the *fan*: three independent projections from a single MC element, with the Riemann zeta entering at the genus projection (via $\mathcal{M}_{1,1}$) and absent from the arity projection.

The $\mathfrak{sl}_2$ intersection. The categorical zeta $\zeta_{\mathfrak{sl}_2}^{\text{DK}}(s) = \zeta(s)$ (Vol I, Proposition ??) is the single point where the four Dirichlet series touch the Riemann zeta function through their defining data. For integrable $V_k(\mathfrak{sl}_2)$: (d) $= \zeta(s)$, the Dirichlet-sewing lift has ζ -factors, and the constrained Epstein (b) at integrable level is a finite Dirichlet polynomial determined by the $k+1$ primary dimensions. But the shadow Dirichlet (c) remains entire and non-classical even for $\mathfrak{sl}_2$ —confirming that the arity axis is structurally different from the genus axis, even in the simplest case.

3I The analytic VOA programme

The preceding analysis identifies a structural gap between the algebraic bar-cobar machinery (which provides integrability via $D^2 = 0$) and the positivity constraints needed for spectral conclusions (Ramanujan bounds, L -value non-vanishing, zero locations). This section develops the *analytic VOA programme*: a framework in which positivity is axiomatized alongside integrability, closing the gap by construction.

3I.1 The integrability–positivity dichotomy

The MC equation $D\Theta + \frac{1}{2}[\Theta, \Theta] = 0$ is an *integrability* constraint (flatness, quadratic consistency). Every spectral conclusion—critical-line zeros, Ramanujan bounds, L -value non-vanishing—requires *positivity* (sign-definiteness, absolute-value bounds). These are logically independent: a flat connection can have eigenvalues of any absolute value.

Three proved obstructions instantiate this dichotomy at genus 1:

- (i) *Structural separation* (Volume I, Theorem ??): the Rankin–Selberg integral $I(s; \mathcal{A})$ is holomorphic at all scattering poles $s = \rho/2$. Unfolding erases the scattering matrix.
- (ii) *Real–complex separation*: the MC equation constrains spectral coefficients on the real spectral axis $s = \frac{1}{2} + it, t \in \mathbb{R}$; zeta zeros live at complex spectral parameters.
- (iii) *Dimensional underdetermination*: the shadow obstruction tower is determined by three real numbers (κ, α, S_4) ; the zeta zeros form a countably infinite set of complex numbers.

All three are **genus-1 theorems**. At genus ≥ 2 , the Fock-diagonal structure breaks (Theorem ??), and the Böcherer bridge (Theorem ??) provides critical-line access to $L(\frac{1}{2}, \pi_f \times \chi_D)$, bypassing unfolding erasure. The remaining gap is **positivity**: the MC equation *determines* central L -values but does not *force* non-vanishing.

31.2 Axiom system: analytic unitary $\text{SC}^{\text{ch}, \text{top}}$ -algebra

Definition 31.1 (Analytic unitary $\text{SC}^{\text{ch}, \text{top}}$ -algebra). A logarithmic $\text{SC}^{\text{ch}, \text{top}}$ -algebra $(\mathcal{A}, \{m_k\}, \{\omega_k\})$ in the sense of Definition ?? equipped with:

(AU1) **Unitarity.** A positive-definite invariant Hermitian form $\langle -, - \rangle_n$ on each conformal weight space H_n , satisfying the BPZ adjoint relation

$$\langle m_2(a, b), c \rangle = \langle a, m_2^*(c, b) \rangle$$

where m_2^* is the BPZ conjugate $Y(e^{zL_1}(-z^{-2})^{L_0}a, z^{-1})$.

(AU2) **Energy bounds.** There exist $C > 0$ and $N \in \mathbb{Z}_{\geq 0}$ such that for all homogeneous $a_1, \dots, a_k$ with $a_i \in H_{\Delta_i}$:

$$\|m_k(a_1, \dots, a_k)\| \leq C^k \prod_{i=1}^k \|a_i\| \cdot (\sum \Delta_i + 1)^N.$$

This is the $\mathcal{A}_\infty$ upgrade of the polynomial OPE growth condition verified for the standard landscape in Theorem ??.

(AU3) **Analytic bar convergence.** The bar complex $B(\mathcal{A})$ admits a Hilbert space completion $B_n^{\text{Hilb}}(\mathcal{A}, q)$ in the q -weighted BPZ norm

$$\|[s^{-1}a_1] \cdots [s^{-1}a_n]\|_q^2 := q^{\sum \Delta_i} \prod_{i=1}^n \|a_i\|_{\Delta_i}^2$$

for each $q \in (0, 1)$. The bar differential d_B is bounded, closable, and has densely defined formal adjoint d_B^* (the BPZ-conjugate creation operator).

(AU4) **Bar Hodge property.** The bar Laplacian $\Delta_B := d_B d_B^* + d_B^* d_B$ is essentially self-adjoint with discrete spectrum on each finite bar degree, and $\ker(\Delta_B) \cong H^*(B(\mathcal{A}))$ (the bar Hodge theorem).

PROPOSITION 31.2 (Essential self-adjointness). For any vertex algebra $\mathcal{A}$ satisfying (AU1), the bar Laplacian Δ_B is essentially self-adjoint on the algebraic bar complex. The spectrum is discrete with finite multiplicities.

Proof sketch. Each weight space $B_n(\mathcal{A})_{\text{weight}=N}$ is finite-dimensional (a basic VOA axiom: $\dim H_N < \infty$). On a finite-dimensional Hilbert space, every symmetric operator is self-adjoint. The full operator $\Delta_B = \bigoplus_{N,n} \Delta_B|_{N,n}$ is an orthogonal direct sum of self-adjoint operators on finite-dimensional spaces, hence essentially self-adjoint on the algebraic direct sum (which is a core for the closure). Discreteness follows from finite-dimensionality of each sector. $\square$

Remark 31.3 (Spectral gap for Koszul algebras). If $\mathcal{A}$ is chirally Koszul, bar cohomology is concentrated on the diagonal (weight = bar degree), so $\ker(\Delta_B|_{N,n}) = 0$ for (N, n) off the diagonal. The smallest nonzero eigenvalue on each off-diagonal sector gives a positive spectral gap $\mu_{N,n} > 0$.

31.3 Families satisfying the axioms

Class	Family	(AU ₁)	(AU ₂)	(AU ₃)	(AU ₄)
G	Heisenberg $\mathcal{H}_\kappa, \kappa > 0$	✓	✓	✓	✓
G	Free $\beta\gamma$	✓	✓	✓	✓
L	$V_k(\mathfrak{g}), k \in \mathbb{Z}_{>0}$	✓	✓	✓	✓*
C	Lattice V_Λ	✓	✓	✓	✓
M	Virasoro discrete series	✓	✓	✓	Likely
M	Virasoro $c > 1$	✓	✓	Open [†]	Open [†]

* At integrable level; generic level requires the resonance-filtered topology.

† Requires the analytic completion for class M (Open Problem at §??).

31.4 The CKLW–Swiss-cheese identification

The Carpi–Kawahigashi–Longo–Weiner (CKLW) functor [?CKLW18] takes a strongly local unitary VOA V and produces a conformal net $\{A(I)\}_{I \subset S^1}$ on the vacuum Hilbert space H_V . The Swiss-cheese framework identifies this functor as the *analytic completion of the open sector* of $\text{SC}^{\text{ch}, \text{top}}$:

$$V \xrightarrow{\text{recognition}} (\mathcal{A}_{\text{ch}}, \mathcal{A}_{\text{top}}) \xrightarrow{\text{open projection}} \mathcal{A}_{\text{top}} \xrightarrow{\text{clutching}} \mathcal{A}_{\text{top}}|_{S^1} \xrightarrow{\text{CKLW}} \{A(I)\}$$

Arrows 1–3 are proved in this volume (Theorems ??, ??, Definition ??(vi)). Arrow 4 is the CKLW theorem [?CKLW18]. The identification explains:

- *Why conformal nets are E_1* : they are the open (topological) colour of $\text{SC}^{\text{ch}, \text{top}}$, with the holomorphic colour integrated out by smearing.
- *Why strong locality is the key hypothesis*: it is the analytic version of E_1 -locality in the open sector.
- *Why DHR sectors match line operators*: both classify modules of the open-sector factorization category. For the affine lineage at integrable level, the Kazhdan–Lusztig equivalence, the CKLW theorem, and the Wassermann construction provide all ingredients: the line-operator category $\mathcal{C}_{\text{line}}^{\text{red}} \simeq \text{Rep}_q(\mathfrak{g})$ (Theorem ??) matches the DHR category of the conformal net. At generic level or for class M algebras, the identification is conjectural and reduces to CKLW’s strong locality hypothesis.

31.5 The Tannakian fibre functor

For a unitary VOA V at integrable level k , the BPZ inner product defines a faithful exact $*$ -monoidal functor

$$\omega_{\text{BPZ}}: \mathcal{C}_{\text{line}}^{\text{int}} \longrightarrow \text{Hilb}.$$

By Tannakian reconstruction, $H = \text{End}(\omega_{\text{BPZ}}) \cong U_q(\mathfrak{g})$ with the compact $*$ -structure ($q = e^{i\pi/(k+h^\vee)}$ on the unit circle). The quantum trace $\text{tr}_q = \text{tr}(K^{2\rho} \cdot)$ is a positive functional (the Haar state), and the GNS Hilbert space is the state space on $S^1 \times D^2$.

The three-tier picture maps precisely:

- Tier (i) (pole-free BD-commutative E_∞ subclass): forgetful functor to Vect, commutative Hopf algebra.
- Tier (ii) (local E_∞ with OPE poles, class L): ω_{BPZ} exists, compact quantum group.
- Tier (iii) (still local E_∞ , class M): **no** fibre functor to Hilb can make the braiding unitary—the $\mathcal{A}_\infty$ tower prevents it (Remark ??).

31.6 The analytic Swiss-cheese operad

The HS-sewing condition (Theorem ??) is not merely a condition on algebras: it defines a topology on the operad $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$ itself. The *analytic Swiss-cheese operad at sewing parameter q* is

$$\mathrm{SC}_q^{\mathrm{ch},\mathrm{top},\mathrm{an}} := L_q^2\text{-completion of } C_*(\mathrm{SC}^{\mathrm{ch},\mathrm{top}}),$$

where the L_q^2 -norm uses the FM volume form and q -weighting by conformal weight. The composition maps extend to bounded operators because $\mathrm{FM}_k(\mathbb{C})$ is compact with corners and the FM Jacobian estimate ensures logarithmic forms are L^1 -integrable.

Equivalence theorem. An algebra satisfies the HS-sewing condition at parameter q if and only if it is an algebra over $\mathrm{SC}_q^{\mathrm{ch},\mathrm{top},\mathrm{an}}$. This makes the analytic condition *operadic* rather than algebra-by-algebra. The entire standard landscape (all seven families) consists of algebras over $\mathrm{SC}_q^{\mathrm{ch},\mathrm{top},\mathrm{an}}$ for every $q \in (0, 1)$ in the checked finite-type cases; outside that range this is a conditional analytic-completion statement.

31.7 The bar trace formula

The bar Laplacian Δ_B admits a heat kernel $\Theta_B(t) = \mathrm{Tr}(e^{-t\Delta_B})$. The *bar trace formula* relates the spectral side (eigenvalues of Δ_B) to a geometric side (a sum over boundary strata of $\mathrm{FM}_k(\mathbb{C})$):

$$\sum_n h(\lambda_n) = h(0) \chi(B^{\mathrm{ann}}) + \sum_{k \geq 2} \sum_{T \in \mathrm{Trees}(k)} \hat{h}(\ell_T) m_T(\mathcal{A}) + \text{planted-forest corrections},$$

where ℓ_T is the bar length of tree T (the weighted sum of collision residues along edges) and $m_T(\mathcal{A})$ is the A_∞ amplitude on the tree stratum D_T . For the Heisenberg algebra, the one-particle reduction recovers the Selberg trace formula: bar geodesics = plumbing parameters, $\ell_n = n$, and $\Theta_B^{\mathcal{H}}(t) = \kappa e^{-t}/(1 - e^{-t})$. The planted-forest corrections vanish for class G and contribute at class L and beyond via the cubic obstruction of Theorem ??.

31.8 IC-purity and Hodge–Riemann positivity

The *collision-weight t -structure* on $D(B^{\mathrm{an}}(\mathcal{A})\text{-comod})$, defined by the weight filtration from Saito’s mixed Hodge module theory, has amplitude equal to the shadow depth $r_{\max}$. On the semisimple-purity locus (classes G, L, C), the heart is expected to carry an IC pairing Q_{IC} on the bar harmonic space, induced by the Hodge–Riemann bilinear relations on IC complexes of the FM compactification (de Cataldo–Migliorini). Definiteness depends on the real form, polarisation, and grading conventions and is not asserted here as an unconditional theorem.

This upgrades IC purity from a *vanishing* statement (weight spectral sequence degenerates $\Rightarrow$ Koszulness) to a *polarised-pairing* statement. A genuine positivity theorem would require the missing real/polarised structure; the analogy with Elias–Williamson positivity is therefore conjectural at this stage.

For class M (Virasoro), Q_{IC} is expected to be *non-definite*—the non-split extensions in $\mathrm{Ext}_{\mathrm{MHM}}^1(\mathrm{gr}^4 L, \mathrm{gr}^2 L)$ from the quartic pole create off-diagonal terms of either sign. The *IC signature* is a new invariant measuring the failure of positivity for non-semisimple monodromy.

31.9 The genus-2 spectral gap programme

The genus-2 bar Laplacian $\Delta_B^{(2)} = d_B^{(2)} (d_B^{(2)})^* + (d_B^{(2)})^* d_B^{(2)}$ inherits a 2×2 block structure from the genus-2 sewing kernel K_2 :

$$\Delta_B^{(2)} = \Delta_B^{\text{diag}} + \Delta_B^{\text{off-diag}},$$

where Δ_B^{diag} is the direct sum of two genus-1 bar Laplacians and $\Delta_B^{\text{off-diag}}$ encodes the inter-handle coupling through the Schur complement $S = K_{q_2} + R_{21}(1 - K_{q_1})^{-1} R_{12}$.

The off-diagonal coupling is exactly the structural mechanism that breaks the genus-1 separation barrier (Remark ??). The **surviving research programme** is:

- (1) Construct $\Delta_B^{(2)}$ explicitly using the genus-2 Fredholm determinant theorem.
- (2) Prove a spectral gap via screening-type inequalities from the off-diagonal coupling.
- (3) Use $\text{Sp}(4)$ representation theory (Arthur packets) to show the spectral gap forces *temperedness*: the Arthur packets for $\text{Sp}(4)$ distinguish Saito–Kurokawa (endoscopic, non-tempered) from stable (tempered). The off-diagonal sewing coupling detects exactly this factorisation structure.
- (4) Temperedness = the Ramanujan bound for $\text{GSp}(4)$ automorphic forms (Weissauer’s theorem for holomorphic cusp forms).

This is the canonical bridge from bar-complex spectral geometry to arithmetic, identified as the most promising direction by the full research campaign. The genus-1 structural obstruction is a *genus-1 theorem*, not an absolute barrier.

31.10 The algebra–geometry–arithmetic trichotomy

The preceding sections establish a precise negative result: the bar complex of a chiral algebra cannot prove the Riemann Hypothesis. But the argument reveals a deeper structural picture that deserves careful articulation, because the *reason* it fails illuminates the relationship between algebra, geometry, and arithmetic more sharply than the failure itself.

31.10.1 Three actors, one meeting point

The partition function $Z(\tau)$ of a chiral algebra $\mathcal{A}$ is the meeting point of three mathematical worlds:

Actor	What it encodes	Source
The bar complex $\overline{B}(\mathcal{A})$	The OPE data of $\mathcal{A}$	Algebra (the chiral product)
The hyperbolic Laplacian Δ_H	The spectral theory of $\mathcal{M}_{1,1}$	Geometry (the modular surface)
The Riemann zeta function $\zeta(s)$	The scattering poles of Δ_H	Arithmetic (the primes)

The bar complex knows everything about $\mathcal{A}$. The spectral theory of $\mathcal{M}_{1,1} = \text{SL}(2, \mathbb{Z}) \backslash \mathfrak{H}$ knows everything about ζ . The partition function $Z(\tau)$ is the object on which both act, but they act on *different aspects* of it: the bar complex determines Z as a q -series (its algebraic content), while Δ_H decomposes Z as a function on a hyperbolic surface (its spectral content).

The bar complex does not encode the zeta zeros. It encodes the *algebra*, which produces $Z(\tau)$ as a convergent q -series $\sum d(n) q^{n-c/24}$. The zeta zeros are a property of how $Z(\tau)$ *sits on* $\mathcal{M}_{1,1}$ --they come from the geometry of the modular surface, not from the algebra of the chiral product. The chain is:

$$\overline{B}(\mathcal{A}) \xrightarrow{\text{OPE data}} Z(\tau) \text{ as } q\text{-series} \xrightarrow{\text{place on } \mathcal{M}_{1,1}} Z(\tau) \text{ as function on } \text{SL}(2, \mathbb{Z}) \backslash \mathfrak{H} \xrightarrow{\Delta_H} \text{spectral decomposition} \ni \zeta \text{ zeros.}$$

The bar complex controls the first arrow. The zeta zeros enter at the last. The gap is the passage from “ Z as a q -series” to “ Z as a function on a hyperbolic surface whose Laplacian has continuous spectrum governed by ζ .”

31.10.2 What encodes the Eisenstein/continuous spectrum

The Roelcke–Selberg decomposition of $\hat{Z}^c = y^{c/2} |\eta|^{2c} Z$ on $\mathcal{M}_{1,1}$ splits L^2 into three parts:

$$\hat{Z}^c(\tau) = c_{\text{res}} + \sum_j \beta_j \varphi_j(\tau) + \frac{1}{4\pi} \int_0^\infty \alpha(t) E_{1/2+it}(\tau) dt,$$

where φ_j are Maass cusp forms (discrete spectrum) and E_s is the Eisenstein series (continuous spectrum). The scattering matrix $\varphi(s) = \Lambda(1-s)/\Lambda(s)$, whose poles are the scaled zeta zeros at $s = \rho/2$, governs the Eisenstein series through $E_s = y^s + \varphi(s) y^{1-s} + \dots$

This scattering matrix is a property of the **hyperbolic Laplacian** $\Delta_H = -y^2(\partial_x^2 + \partial_y^2)$ on the non-compact surface $\text{SL}(2, \mathbb{Z}) \backslash \mathfrak{H}$. It is *pure spectral geometry*: it exists independently of any chiral algebra, any partition function, or any physical theory. The zeta zeros are built into the geometry of the modular surface through the Euler product of $\zeta(s)$, which encodes the distribution of primes, which controls the arithmetic of the lattice $\text{SL}(2, \mathbb{Z})$ acting on $\mathfrak{H}$.

The bar complex of $\mathcal{A}$ knows nothing about this geometry. It produces $Z(\tau)$ as a q -series; what happens when that q -series is placed on the modular surface and decomposed spectrally is a question about the *surface*, not about the *algebra*.

31.10.3 What the CFT “knows”

If the zeta zeros are encoded in the spectral decomposition of $Z(\tau)$ on $\mathcal{M}_{1,1}$ (the content of Benjamin–Chang [?BenjaminChang22]), then what CFT property corresponds to the zeros? The answer is precise:

The zeros control the equidistribution rate of $Z(\tau)$ on the modular surface.

The Eisenstein spectrum governs how fast a function on $\mathcal{M}_{1,1}$ approaches its average under modular averaging. For $Z(\tau)$ with $d(n) \geq 0$ (unitarity), the equidistribution rate is controlled by the spectral gap λ_1 of Δ_H on the appropriate congruence quotient--and this spectral gap *is* the Selberg eigenvalue conjecture ($\lambda_1 \geq \frac{1}{4}$), which *is* the Ramanujan conjecture for $\text{GL}(2)$ Maass forms.

The CFT does not “know” where the zeros are through its algebraic structure (the bar complex, the OPE, the MC equation). It “knows” through its **equidistribution rate on the moduli space**--a property that requires the full analytic structure of $Z(\tau)$ as a function on a hyperbolic surface, not just its q -expansion coefficients.

31.10.4 Why the analytic VOA programme is the right direction

This analysis identifies what is missing from the algebraic framework and what an analytic upgrade would need to provide.

The bar complex gives you the q -series. What you need is the *hyperbolic geometry of the function that q -series defines*: its growth, its equidistribution, its spectral decomposition. The passage from q -series to hyperbolic geometry requires:

- (i) *A positive-definite inner product* on the function space (axiom AU₁), to define the Hilbert space $L^2(\mathcal{M}_{1,1})$ on which Δ_H acts.
- (ii) *Growth bounds* on $Z(\tau)$ as $\text{Im}(\tau) \rightarrow \infty$ (axiom AU₂), to place Z in the correct Sobolev space.
- (iii) *Convergence of the spectral decomposition* (axiom AU₃), to make the Roelcke–Selberg expansion meaningful.
- (iv) *Spectral gap control* (axiom AU₄), to quantify the equidistribution rate.

These are precisely the axioms (AU₁)–(AU₄) of the analytic unitary $\text{SC}^{\text{ch}, \text{top}}$ -algebra (Definition 31.1). The analytic VOA programme does not attempt to make the bar complex see the zeta zeros—it cannot, because the zeros are geometric, not algebraic. Instead, it provides the analytic infrastructure to study how $Z(\tau)$, produced by the bar complex, *sits on the modular surface*—the meeting point where algebra, geometry, and arithmetic converge.

31.10.5 The Steinberg principle

The Steinberg variety presents the Hecke algebra. The bar complex presents the Swiss-cheese algebra. Neither presents the Riemann zeta function. The zeta function is presented by the *modular surface itself*—its spectral theory, its scattering matrix, its Selberg trace formula. The correct analogy is not “the bar complex is to ζ as the Steinberg variety is to Hecke,” but rather: the bar complex and ζ are two sides of the partition function, meeting at $Z(\tau)$ on $\mathcal{M}_{1,1}$, as the Steinberg variety and the Springer resolution are two sides of the flag variety, meeting at the moment map.

The bar complex is the algebraic side: it produces the function. The hyperbolic Laplacian is the geometric side: it decomposes the function. The Riemann Hypothesis is the conjecture that these two sides interact in the most harmonious possible way—that the algebraic function produced by the bar complex equidistributes on the geometric surface at the optimal rate. Whether this harmony holds is a question about the *relationship* between algebra and geometry, not a question answerable from either side alone.

32 The graviton is composite

The Sugawara stress tensor

$$T = \frac{1}{2(k + h^\vee)} \sum_a J^a J_a$$

is quadratic in affine currents. It is not a fundamental field. The graviton is composite.

The BRST complex of the Drinfeld–Sokolov reduction remembers this: the transferred coproduct is strictly primitive (Theorem 12.1, equation (6)). No cross-term, no splitting, at every arity and every principal DS reduction.

*

In gauge theory: the gluon J^a IS the connection. Fundamental. Ghost number 0. No passage through h . The BRST homotopy does not obstruct the transferred coproduct. The Casimir cross-term survives projection:

$$\Delta_z(T_{\text{aff}}) = \tau_z(T_{\text{aff}}) \otimes 1 + 1 \otimes T_{\text{aff}} + \frac{1}{k + h^\vee} \Omega(w+z, w),$$

where $\Omega = \sum_a J^a \otimes J_a$ is the split Casimir. A production vertex. A gluon bound state dissociates.

In gravity: the graviton T IS the curvature. Composite. Ghost-burdened. Every HPL tree at ghost number 0 dies under projection. Gravitons do not split. They braid.

*

The r -matrix $r^{\text{Vir}}(z) = (c/2)/z^3 + 2T/z$ carries all gravitational scattering. The cubic pole: the bar kernel $d \log(z - w)$ absorbs one power from the quartic OPE. The Virasoro OPE has poles at z^{-4} , z^{-2} , z^{-1} . The r -matrix has poles at z^{-3} , z^{-1} . The logarithmic derivative is always one degree milder than the function itself. This absorption is not an approximation. It is the structural content of calling the bar construction a categorical logarithm.

*

The five-theory comparison (see §25) confirms the pattern: DS reduction creates depth ($L \rightarrow M$) and kills the coproduct. The distinction is structural (the ghost-number filtration), not parametric (the central charge).

*

The bar complex of a chiral algebra isolates algebraic data that ordinary perturbative expansions do not package canonically.

It supplies the scalar genus- g free energy in closed form: $F_g = (c/2) \cdot \lambda_g^{\text{FP}}$, the $\hat{A}$ -genus coefficients times the modular characteristic.

It supplies the shadow tower of higher-arity corrections, as the Taylor expansion of an algebraic function of degree 2: $H(t) = t^2 \sqrt{Q_{\text{Vir}}(t)}$, three numbers (κ, α, S_4) , one quadratic form, one square root.

It gives the DS-transfer no-cross-term criterion (§12): under the ghost-number tree condition, the algebraic shadow has no splitting coproduct.

It records a precise arithmetic shadow. At rational central charge c_0 , the shadow metric Q_{Vir} specialises to a specific quadratic polynomial over $\mathbb{Q}$, and $K_{\text{ct}}(c_0) = \mathbb{Q}(\sqrt{d(c_0)})$ is a specific real quadratic contact field (the contact square-class $\Delta_{\text{ct}} = 40/(5c+22) > 0$ for $c > 0$). The chiral Cardy contribution $2\pi\sqrt{c\Delta}/6$ is the leading coefficient. The polynomial discriminant $\text{disc}(Q_{\text{Vir}}) = -320c^2/(5c+22) < 0$ ensures the shadow obstruction tower is infinite (complex conjugate roots); the contact square-class $\Delta_{\text{ct}} > 0$ produces a real quadratic contact extension. The class number of $K_{\text{ct}}(c_0)$ measures the arithmetic complexity of gravity at that central charge. The Ising model lives over $\mathbb{Q}(\sqrt{5})$ (§29). The self-dual gravity at $c = 13$ lives over $\mathbb{Q}(\sqrt{870})$, and the complementarity constant $6960 = 2^4 \cdot 3 \cdot 5 \cdot 29$ appears in the numerator of $\Delta_{\text{ct}}(c) + \Delta_{\text{ct}}(26-c)$.

*

The bar complex of a chiral algebra is a 1-form, a square root, and a ghost.

The 1-form $\eta = d \log(z_i - z_j)$ extracts the OPE. Arnold's relation makes it nilpotent. The genus-completed differential $D_{\mathcal{A}}$ satisfies $D_{\mathcal{A}}^2 = 0$, and $\Theta_{\mathcal{A}} = D_{\mathcal{A}} - d_0$ is the universal MC element.

The square root $\sqrt{Q_L}$ generates the tower. One quadratic form, one algebraic function, infinitely many rational invariants. The depth classification, the growth rate, the convergence behaviour, the Galois theory, the Epstein zeta function, the discriminant complementarity: all are properties of this single square root.

The ghost kills the splitting (Theorem 12.1): the BRST homotopy carries ghost number ± 1 , the projection annihilates it, and the coproduct vanishes.

Everything else is a projection of these three.

33 Koszul–Epstein and quantum gravity

33.1 The arithmetic content of the gravitational bar complex

The bar complex of the Virasoro algebra at central charge c carries three layers of arithmetic data.

Layer 1: the Heisenberg core. The Miura map $\hat{Y}: \mathcal{W}_{\kappa}(\mathfrak{sl}_2) \rightarrow V^{\mathfrak{h}_{\kappa}}(\mathfrak{h})$ embeds the Virasoro algebra into a rank-1 Heisenberg. At the level of the sewing determinant, this produces an exact Euler product:

$$\sum_{N \geq 1} \sigma_{-1}(N) q^N = -\log(\eta(q)^2) - \frac{\tau}{12}, \quad \sum_{N \geq 1} \sigma_{-1}(N) N^{-s} = \zeta(s) \zeta(s+1).$$

The Heisenberg core is arithmetically transparent: all nontrivial genus-one arithmetic is a consequence of the divisor function σ_{-1} being multiplicative.

Layer 2: the Miura defect. The vacuum character of W_N splits as $\chi_{W_N}^{\text{vac}}(q) = \chi_H(q)^{N-1} \cdot \prod_{m=1}^{N-1} (1 - q^m)^{N-m}$. All nontrivial genus-one arithmetic beyond the Heisenberg core sits in the finite Miura defect factor $D_N(q) = \prod_{m=1}^{N-1} (1 - q^m)^{N-m}$. For $N = 2$ (Virasoro): $D_2(q) = 1 - q$, removing the weight-1 mode.

Layer 3: the shadow obstruction tower. The infinite shadow obstruction tower $\{S_r(c)\}_{r \geq 2}$, determined by (κ, α, S_4) via the MC recursion, encodes the full $\mathcal{A}_{\infty}$ deformation data. Its spectral measure ρ is uniquely determined by the Carleman condition. The MC recursion propagates Hecke equivariance from the character level to all arities (Route C, proved for the standard landscape).

33.2 The gravitational dichotomy and the Koszul–Epstein frontier

The gravity dichotomy at $c = 26$ concerns the vanishing of $\kappa_{\text{eff}} = \kappa(\text{matter}) + \kappa(\text{ghost})$. The Koszul–Epstein question concerns the critical-line properties of the arithmetic shadow. These are unrelated:

- $\kappa_{\text{eff}} = 0$ at $c = 26$ determines whether the genus tower terminates (the Clifford-to-exterior degeneration of the transgression algebra).
- The critical-line question concerns the zeros of $\zeta(s)$ appearing in the Heisenberg sewing determinant. These zeros are independent of the central charge: the sewing lift $S_{\text{Vir}}(u) = \zeta(u+1)(\zeta(u) - 1)$ is the same function for all c .

The Koszul self-duality point $c = 13$, where $\kappa + \kappa' = 13$ and $\delta_{\kappa} = 0$, is the point where Verdier–Hecke commutation forces the constrained Epstein zeta to factor into standard L -functions. This is a genuine

arithmetic structure of the self-dual gravitational theory. It does not, however, produce a critical-line theorem.

33.3 Honest assessment

The MC element $\Theta_{\mathcal{A}}$ of the gravitational bar complex produces genuine arithmetic structure: the Carleman-determined spectral measure, Route C prime-locality, the shadow–spectral correspondence for lattice VOAs, the Verdier–Hecke factorisation at self-dual points. These are proved theorems.

The programme does not produce a critical-line theorem. The structural obstruction is that the shadow spectral measure and the automorphic spectral measure are different objects, and the map between them (the Rankin–Selberg integral) is not sign-preserving. No mechanism for positivity has been identified. The bar–cobar homotopy equivalence provides deformation-theoretic transport, not arithmetic positivity.

The surviving content: the quartic resonance class $R_4^{\text{mod}}(\mathcal{A})$ is the first nonlinear place where Koszul duality constrains the automorphic spectral decomposition beyond the character level. Whether this constraint carries critical-line information is open. The correct next computation is the quartic Gram-side matching with the crossing-weighted bilinear residue kernel (using actual DOZZ/Toda structure constants), not the bare spectral measure (which fails by four to five orders of magnitude).

The bar complex of a chiral algebra knows the exact genus tower, the arithmetic of the shadow, and the depth classification. It does not know the zeros of $\zeta(s)$.

34 Spectrum and gravity

The gravitational bar complex carries three kinds of data: the algebraic engine (Theorems A–H, the MC element $\Theta_{\mathcal{A}}$), the arithmetic shadow (the shadow obstruction tower, the depth classification, the Epstein zeta), and the spectral content (the primary spectrum, the partition function, the constrained Epstein series ε_s^c). These three overlap but do not coincide. This section records the definitive assessment of their relationship in the gravitational context.

34.1 The spectrum as a categorical invariant

The scalar primary spectrum $\text{Spec}_{\text{sc}}(\mathcal{A}) = \{(\Delta_i, m_i)\}$ of a 2d CFT at central charge c is an invariant of the *modular tensor category* $\mathcal{A}\text{-mod}^{\text{ss}}$ together with the modular-invariant partition function $Z(\tau, \bar{\tau}) = \sum_{i,j} M_{ij} \chi_i(\tau) \overline{\chi_j(\tau)}$. The multiplicity matrix M_{ij} encodes the physical spectrum; the characters χ_i encode the algebraic spectrum.

The bar complex $B(\mathcal{A})$ is built from the algebra $\mathcal{A}$ (specifically, from the vacuum module and its OPE), not from the category of modules. The bar-cobar machine determines the Koszul dual $\mathcal{A}^!$, the MC element $\Theta_{\mathcal{A}}$, and the shadow tower $\{S_r\}$. It does *not* determine the modular S -matrix or the multiplicity matrix. The primary spectrum is therefore external to the bar construction.

For the gravitational theory (Virasoro at central charge c), the vacuum module is the unique irreducible highest-weight module $L(c, 0)$, and the partition function $Z_{\text{grav}} = |\chi_0(\tau)|^2 + \sum_{h>0} m_h |\chi_h(\tau)|^2$ depends on the dynamical data $\{m_h\}_{h>0}$: the spectrum of primary states. The bar complex of Vir_c sees the algebra, not the specific gravity theory built from it.

34.2 Which constructions partially capture the spectrum

Five constructions each capture a shadow of the gravitational primary spectrum. None captures it fully from within the bar machine.

- (i) *Zhu's algebra* $A(\text{Vir}_c)$. For the universal Virasoro: $A(V_c) \cong \mathbb{C}[x]$. The simple modules of $\mathbb{C}[x]$ correspond to points $x = h \in \mathbb{C}$: the conformal dimensions. Zhu's algebra determines the *set* of allowed lowest weights $\{h_{r,s}\}$ for the minimal model at $c = c_{p,q}$ (via the quotient $A(L(c, 0)) = \mathbb{C}[x]/(f_c(x))$). But it does not determine the partition function multiplicities. At generic c (irrational, or rational non-minimal), $A(V_c) = \mathbb{C}[x]$ admits a continuum of simple modules, and no finite selection rule from $A(V_c)$ picks out the physical spectrum.
- (ii) *Associated variety* X_{Vir_c} . For Virasoro: $X_{V_c} = \mathbb{C}$ (one-dimensional, since Virasoro has a single strong generator). The dimension of X_V controls the asymptotic growth of the character and hence the leading pole of the constrained Epstein series at $s = c/2$. This is the Cardy regime: $\log \rho(E) \sim 2\pi\sqrt{c} E/3$ for large conformal dimension E .
- (iii) *Bar cohomology* $H^*(B(\text{Vir}_c))$. Concentrated in bar degree 1 (Koszulness). The graded dimensions $\dim H^1(B(\text{Vir}))_h$ count generators of the Koszul dual $\text{Vir}_{26-c}^!$ at weight h . These are the *Motzkin differences* $M(h+1) - M(h)$, supported only at even weights, independent of c , and growing as $3^{h/2}$. The quasi-primary count (partitions minus descendants) is a different sequence, nonzero at odd weights and growing as $e^{\pi\sqrt{2h/3}}$. Bar cohomology sees the dual algebra, not the spectrum.
- (iv) *Shadow obstruction tower* $\{S_r\}$. The shadow obstruction tower extracts three numbers (κ, α, S_4) from the OPE and packages them into the shadow metric Q_L . The shadow-metric Epstein zeta $\varepsilon_{Q_L}(s)$ is a binary quadratic form sum, unrelated to the primary spectrum except through a chain of projections. For lattice VOAs, the shadow–spectral correspondence recovers the full L -function package; for Virasoro, the correspondence is incomplete (the shadow has 3 parameters; the spectrum has infinitely many).
- (v) *The chiral derived centre* $\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A})$. The universal bulk algebra, built as chiral Hochschild cochains $C_{\text{ch}}^\bullet(\mathcal{A}_b, \mathcal{A}_b)$, classifies bulk operators. Its cohomology controls the BRST-closed observables of the 3d HT theory. But it is a genus-0 invariant of the open/closed Swiss-cheese structure, and does not directly encode the genus-1 partition function. The trace on the derived centre (the annulus trace $\text{Tr}_{\mathcal{A}}$) recovers the Hochschild homology $\text{HH}_*(\mathcal{A})$, which is the first modular shadow of the open sector. This is related to, but not identical with, the partition function.

34.3 The gravitational spectral gap

In the gravitational context, the primary spectrum has additional structure: the conformal bootstrap imposes crossing-symmetry constraints on the four-point function, which restrict the allowed $\{(\Delta_i, m_i)\}$ beyond what the chiral algebra alone determines. The Benjamin–Chang constrained Epstein series ε_s^ζ is the Eisenstein spectral coefficient of $\hat{Z}^\zeta$, and its functional equation involves $\zeta(2s)/\zeta(2s-1)$, introducing poles at $s = (1 + \rho_n)/2$ where ρ_n are nontrivial zeros of ζ .

The pole *locations* are universal: they come from $\zeta(2s-1) = 0$ in the Γ -factor ratio $F_c(s)$, and do not depend on the specific CFT. The pole *residues* are CFT-specific: they are integrals of the primary-counting function against residues of Eisenstein series on the modular fundamental domain. The bar complex constrains neither the locations (which are number-theoretic: the zeros of ζ) nor the residues (which are spectral: the primary multiplicities m_h).

For the gravitational theory at $c = 26$ (critical string): $\kappa_{\text{eff}} = \kappa(\text{matter}) + \kappa(\text{ghost}) = 0$, and the genus tower terminates. But the primary spectrum is still infinite (the Virasoro module at $c = 26$ has infinitely many primaries at all weights $h \geq 2$), and ε_s^{26} is a nontrivial Dirichlet series. The genus tower's termination is a statement about the $\hat{A}$ -genus factor κ ; it says nothing about the spectral content.

For the gravitational theory at $c = 13$ (self-dual point): Verdier–Hecke commutation forces the constrained Epstein to factor into standard L -functions. This is the strongest structural result: self-duality of the chiral algebra produces a factorisation of the spectral invariant. But even at $c = 13$, the factorisation does not determine the zeros of the constituent L -functions.

34.4 Is ε_s^c a bar-complex invariant?

PROPOSITION 34.1 (*The constrained Epstein is not a bar-complex invariant*). The constrained Epstein series $\varepsilon_s^c(\mathcal{A})$ cannot be reconstructed from the bar complex $B(\mathcal{A})$ and its cohomology.

Proof. Three independent arguments.

(a) Categorical argument. Two non-isomorphic modular-invariant partition functions for the same chiral algebra produce different constrained Epstein series. Example: the Ising model ($c = 1/2$) has the diagonal partition function $Z_{\text{diag}} = |\chi_0|^2 + |\chi_{1/2}|^2 + |\chi_{1/16}|^2$ and the charge-conjugation partition function (which is the same, since Ising is self-conjugate). But for $\widehat{\mathfrak{su}}(2)_k$ at $k \geq 10$, there exist exceptional modular invariants (the D -type and E -type classifications of Cappelli–Itzykson–Zuber) that produce different primary spectra from the same chiral algebra. The bar complex $B(\hat{\mathfrak{g}}_k)$ is the same for all choices of modular invariant; the constrained Epstein series differs.

(b) Dimensional argument. The bar complex is determined by the OPE data of the vacuum module (a countable set of structure constants). The primary spectrum is determined by the modular invariant *and* the full representation theory (the braided tensor structure, the modular S -matrix). The latter is strictly richer: two algebras with the same OPE but different categories of modules (e.g., $V_k(\mathfrak{g})$ at the same k but with different conformal extensions) have the same bar complex but different spectra.

(c) Weight argument. $\dim H^1(B(\text{Vir}))_h$ at odd h vanishes (the Koszul dual has generators only at even weights), while the quasi-primary count at odd h is generically nonzero. No Dirichlet series built from bar cohomology dimensions can reproduce ε_s^c , which sums over all primary weights including odd ones. $\square$

34.5 The honest three-layer picture

The gravitational bar complex produces three layers of arithmetic data, each genuine and proved.

Layer 1: the genus expansion. $F_g(\mathcal{A}) = \kappa(\mathcal{A}) \cdot \lambda_g^{\text{FP}}$ for uniform-weight algebras. This is the leading scalar projection of the MC element $\Theta_{\mathcal{A}}$, generated by $\hat{A}(i\hbar) - 1$. It captures *one number* (κ) from the full partition function.

Layer 2: the shadow obstruction tower. $\{S_r\}_{r \geq 2}$, determined by (κ, α, S_4) . This captures *three numbers* from the OPE, packaged into the shadow metric Q_L and the quadratic extension K_L . The shadow–spectral correspondence for lattice VOAs, Route C prime-locality, and the Verdier–Hecke factorisation are genuine arithmetic results at this layer.

Layer 3: the spectral content. $\varepsilon_s^c(\mathcal{A}) = \sum (2\Delta)^{-s}$, encoding the full scalar primary spectrum. This layer is external to the bar complex: it requires the partition function, which is a genus-1 categorical invariant, not a genus-0 algebraic one.

The gap between Layers 2 and 3 is the gap between the shadow obstruction tower (genus-0, 3 parameters) and the primary spectrum (genus-1, ∞ parameters). No mechanism in the MC equation or the bar-cobar machine bridges this gap: the shadow obstruction tower is determined by finitely many OPE coefficients, while the spectrum encodes infinitely many independent quantities.

The honest statement for the gravitational theory: *the bar complex of the Virasoro algebra at central charge c determines the exact genus expansion $F_g = (c/2) \lambda_g^{\text{FP}}$, the infinite shadow tower with growth rate $\rho(c)$ and discriminant $\Delta = 80/(5c+22)$, and the four-class depth assignment (class M for all $c \neq 0$). It does not determine the primary spectrum, the partition function, or the constrained Epstein series. The spectrum is a representation-theoretic invariant; the bar complex is an algebra-theoretic invariant. They live in different categories.*

35 Derived global sections in quantum gravity

The gravitational bar complex defines a sheaf on moduli space whose derived global sections are algebraic invariants. This section records the definitive assessment of what these algebraic invariants capture in the gravitational context, correcting the false claim that “the bar complex cannot see the spectrum because integration over moduli space is analytic.”

35.1 The sheaf-theoretic framework

For Virasoro at central charge c , the bar complex at genus g defines a sheaf of dg modules on $\overline{\mathcal{M}}_g$. The key objects:

- (i) The *virtual bar K-class* $V_{\text{Vir}_c} := [R\pi_{g*} \overline{B}^{(g)}(\text{Vir}_c)] \in K^0(\overline{\mathcal{M}}_g)$, computed by derived pushforward along the universal curve. This is well-defined in the perfect finite-type standard-landscape cases checked here: the perfectness criterion (Koszul acyclicity + finite-dimensional fiber cohomology) is assumed outside that range. Critical-level and non-perfect fibres require separate coderived treatment.
- (ii) The *center sheaf* $\mathcal{Z}_{\text{Vir}_c} := R^*\pi_{g*}(\overline{B}^{(g)}, d_{\text{fib}})$, a constructible complex on $\overline{\mathcal{M}}_g$ whose restriction to each smooth finite-type stratum is a local system with fiber $H_*^{\text{ch}}(\Sigma_g, \text{Vir}_c)$.
- (iii) The *ambient complex* $C_g(\text{Vir}_c) = R\Gamma(\overline{\mathcal{M}}_g, \mathcal{Z}_{\text{Vir}_c})$, the derived global sections. This is a purely algebraic operation on a constructible sheaf over a proper DM stack.
- (iv) The *GRR hierarchy*:

$$\begin{aligned} c_1(\det V_{\text{Vir}_c}) &= \frac{c}{2} \cdot \lambda, \\ \text{ch}(V_{\text{Vir}_c}) &\leftrightarrow \Delta_{\text{Vir}}(x) \quad (\text{Motzkin differences}), \\ \text{Hol}(V_{\text{Vir}_c}) &= \Pi_{\text{Vir}_c} \quad (\text{MCG monodromy}). \end{aligned}$$

All three levels are algebraic.

So the bar complex *does* produce algebraic invariants from integration over moduli space. The claim that this integration is “analytic, not algebraic” was a false idea. Derived global sections, Chern character, GRR pushforward, and monodromy representation are all algebraic operations.

35.2 The gravitational spectral gap: precise diagnosis

The GRR hierarchy captures the *algebra's* modular structure. It does not capture the *gravitational spectrum*. The precise diagnosis:

(i) **The GRR scalar level** recovers $\kappa(\text{Vir}_c) = c/2$. This is one number. The gravitational partition function $Z(\tau, \bar{\tau}) = |\chi_o(\tau)|^2 + \sum_{h>o} m_h |\chi_h(\tau)|^2$ encodes infinitely many numbers $\{m_h\}$.

(ii) **The GRR spectral level** recovers the bar cohomology dimensions $\dim H^1(B(\text{Vir}))_h$, which are the Motzkin differences $M(h+1) - M(h)$. These count generators of the Koszul dual $\text{Vir}_{26-c}^!$, not primaries of Vir_c . The two sequences differ: bar cohomology is supported only at even weights and is c -independent; the quasi-primary count is nonzero at odd weights and depends on the specific gravity theory.

(iii) **The GRR holonomy level** recovers the monodromy of $\mathcal{Z}_{\text{Vir}_c}$: the action of the mapping class group on chiral homology. For the Virasoro algebra, this is the monodromy of the KZ connection, which encodes the projective representation of $\text{MCG}(\Sigma_g)$ on the space of conformal blocks. This is an invariant of the *algebra* (it is functorial in morphisms of chiral algebras, not in changes of the module category or modular invariant).

The obstruction is not analysis vs. algebra. It is *algebra vs. category*: the bar complex sees the chiral algebra Vir_c ; the gravitational spectrum sees the choice of gravity theory built from Vir_c (the specific multiplicities $\{m_h\}$ in the partition function, which are dynamical data external to the algebra).

35.3 Three routes toward the spectrum

35.3.0.1 (a) Module bar construction. The module bar complex $\overline{B}_{\text{Vir}_c}(L(c, h))$ applied to each irreducible module $L(c, h)$ produces a comodule over $\overline{B}(\text{Vir}_c)$. Its K -class carries the conformal dimension h . Summing with the gravitational multiplicities $\{m_h\}$:

$$\sum_h m_h \text{ch}(R\pi_{1*} \overline{B}_{\text{Vir}_c}(L(c, h)))$$

would recover the gravitational partition function at genus 1. But this takes $\{m_h\}$ as *input*: it computes the partition function from the spectrum, rather than extracting the spectrum from the bar complex.

35.3.0.2 (b) Conformal blocks as D -module. The conformal blocks local system on $\mathcal{M}_{g,n}$ carries a flat connection (the KZ/Hitchin connection) whose monodromy encodes the modular S -matrix for rational theories. At integrable level for affine Kac–Moody algebras, the monodromy recovers the primary dimensions via the Verlinde formula.

For the Virasoro algebra at generic c , the conformal blocks local system has irregular singularities and the representation theory is non-semisimple (at irrational c , all Verma modules are irreducible and the spectrum is continuous). Whether the D -module structure of the conformal blocks sheaf on $\overline{\mathcal{M}}_{1,1}$ determines the gravitational spectrum (after choosing a modular invariant) is a frontier question: it amounts to recovering the spectral decomposition of a function on $\text{SL}(2, \mathbb{Z}) \backslash \mathfrak{H}$ from the algebraic structure of its associated D -module.

35.3.0.3 (c) The Roelcke–Selberg step. The passage from the partition function $Z(\tau, \bar{\tau})$ to the constrained Epstein series ε_s^c uses the spectral decomposition of $L^2(\text{SL}(2, \mathbb{Z}) \backslash \mathfrak{H})$ into Eisenstein series and Maass cusp forms. This involves the hyperbolic Laplacian, which is a real-analytic operator. The

scattering matrix involves $\zeta(2s)/\zeta(2s-1)$, whose poles are the nontrivial zeros of the Riemann zeta function. No categorical or motivic construction is known to produce this spectral decomposition.

The “analytic” step that is genuinely unavoidable is this last one: from characters (which are algebraic for rational VOAs) to spectral coefficients (which require harmonic analysis on $\mathrm{SL}(2, \mathbb{Z}) \backslash \mathfrak{H}$).

35.4 Honest status

- (a) The bar complex defines a sheaf on $\overline{\mathcal{M}}_g$ with algebraic invariants ($R\Gamma$, ch , Hol , GRR). The claim “integration is analytic” was a false idea.
- (b) These algebraic invariants capture the algebra’s modular structure: κ , bar cohomology dimensions, KZ/Hitchin monodromy. They do *not* capture the gravitational spectrum $\{m_h\}$ or the constrained Epstein ε_s^c .
- (c) The obstruction is *algebra vs. category*, not analysis vs. algebra. Two gravity theories with the same Virasoro algebra but different spectra have the same bar complex. This is a theorem, not a technical limitation.
- (d) The construction that does capture the spectrum—the conformal blocks D -module on $\mathcal{M}_{g,n}$ —is algebraic (Beilinson–Drinfeld) but requires the module category as input. For rational theories, its monodromy (S -matrix) determines the primary dimensions. For non-rational theories, the D -module has irregular singularities and the spectral question is at the frontier of geometric Langlands and irregular Hodge theory.
- (e) The single genuinely analytic step is the Roelcke–Selberg decomposition: from characters to spectral zeta. This step is universal (it involves the Riemann zeta function, not the specific VOA) and has no known categorical substitute.
- (f) Status: the “spectral question” is **OPEN** in the sense that the algebraic D -module framework exists but has not been carried through for Virasoro at generic c . The gap is not a missing construction but a missing computation: does the irregular D -module structure of the Virasoro conformal blocks local system on $\overline{\mathcal{M}}_{1,1}$ determine the primary spectrum after choosing a modular invariant?

36 Complex parameters in quantum gravity

The gravitational bar complex of the Virasoro algebra produces real spectral data: the modular characteristic $\kappa = c/2$, the shadow obstruction tower $\{S_r(c)\}$, and the genus expansion $F_g = \kappa \lambda_g^{\mathrm{FP}}$ are all rational functions of the central charge c . The zeros of the Riemann zeta function, which appear in the scattering matrix of the Eisenstein spectral decomposition on $\mathcal{M}_{1,1}$, live at complex spectral parameters. This section records the definitive assessment of whether any extension of the bar complex can access complex spectral data.

36.1 The structural obstruction

The obstruction is a theorem with three components.

- (i) The shadow obstruction tower on a single primary line is determined by three genus-0 OPE invariants (κ, α, S_4) via Theorem ??: the generating function $H(t) = t^2 \sqrt{Q_L(t)}$ is algebraic of degree 2. Three numbers constitute a finite-dimensional algebraic datum.

- (ii) The zeta zeros $\{\rho_n = \frac{1}{2} + i\gamma_n\}$ constitute a countably infinite collection of complex numbers, believed to be algebraically independent. No finite-dimensional algebraic structure determines such a set.
- (iii) The Rankin–Selberg unfolding that connects the partition function to the constrained Epstein ε_s^c erases the convolution-algebraic structure of the MC equation. The unfolded integral depends on Fourier coefficients alone, not on the MC brackets. The L -functions $L(s, f_j)$ in the spectral decomposition are properties of the eigenforms f_j , independent of the algebra $\mathcal{A}$.

36.2 Eight candidate bridges: the census

A complete investigation examined eight approaches to bridging the gap from real bar-complex data to complex L -function zeros.

36.2.0.1 Dead ends (five). Deligne categories, Wick rotation in c , resonance/MC₄ completion, Borel resummation, and spectral curves. Each fails for a precise reason: Deligne categories interpolate in a categorical variable, not a spectral one; Wick rotation changes the shadow coefficients but not the sewing lift $S_{\mathcal{A}}(\mathcal{U})$, which is c -independent; MC₄ completion solves a homological algebra problem, not a number-theoretic one; Borel resummation requires factorial divergence that the shadow series does not exhibit; and spectral curves encode genus-0 OPE data, not the automorphic spectrum.

36.2.0.2 Genuine mathematics, no bridge (two). The analytic continuation of the shadow obstruction tower and the analytic Langlands programme produce real mathematical content but do not bridge the real-to-complex gap. The shadow obstruction tower continuation produces quadratic number fields (the Galois structure of the shadow extension K_L/F , with discriminant $\text{disc}(Q_L) = -320c^2/(5c+22)$ for Virasoro). The analytic Langlands provides the correct framework for the critical-level oper/shadow interpolation. Both operate on the function-field (geometric) side; the number-field (arithmetic) descent remains the deepest unsolved problem.

36.2.0.3 The most compatible approach (one). The Connes–Marcolli non-commutative geometry programme has the closest structural compatibility with the bar construction: the Bost–Connes system has a Hecke algebra of symmetries compatible with Verdier–Hecke commutation, and the Weil positivity criterion is a trace-class condition on a specific operator. At the self-dual point $c = 13$, Verdier self-duality provides an involution on the factorisation coalgebra that could in principle feed into the non-commutative trace formula. In practice, the arithmetic descent (the bar complex is defined over $\mathbf{C}$, the Bost–Connes system over $\mathbf{Q}$) blocks the construction.

36.3 What the gravitational bar complex provides

The bar complex of the Virasoro algebra at central charge c provides five kinds of arithmetic data, all proved.

- (i) The exact genus expansion $F_g = (c/2) \lambda_g^{\text{FP}}$ at all genera.
- (ii) The infinite shadow obstruction tower with growth rate $\rho(c) = \sqrt{(36 + 2\Delta)/(c^2)}$ and discriminant $\Delta = 80/(5c+22)$.
- (iii) The four-class depth assignment (class M for all $c \neq 0$).

- (iv) The quadratic number field $K_L = \mathbf{Q}(\sqrt{\text{disc}(Q_L)})$ at each rational c , with class numbers ranging from $h = 1$ (models (9, 10) and (24, 25)) to $h = 3008$ (model (28, 29)).
- (v) Route C prime-locality: the MC recursion propagates Hecke equivariance from low-arity character data to all arities.

None of these constrains the zeros of the Riemann zeta function or any standard L -function. The constraints are algebraic (on OPE coefficients and their MC recursions); the zero locations are analytic (determined by the Euler product and the functional equation, not by the OPE).

36.4 The gravitational dichotomy and the spectral divide

The gravity dichotomy (critical string $c = 26$ versus non-critical $c \neq 26$) is a statement about the *vanishing* of a specific class: $\kappa_{\text{eff}} = \kappa(\text{matter}) + \kappa(\text{ghost}) = 0$ if and only if $c = 26$. The self-dual point $c = 13$ is where the Koszul asymmetry $\delta_\kappa = \kappa - \kappa' = 0$ vanishes. These are different conditions at different central charges.

The gravity dichotomy operates on the *algebraic* axis: whether the Clifford algebra $\text{Cliff}(V, \lambda)$ with $\lambda = \kappa(\mathcal{B}) \omega_g$ degenerates to an exterior algebra ($\lambda = 0$ at $c = 26$) or remains a matrix algebra ($\lambda \neq 0$ at $c \neq 26$). This is a statement about the transgression algebra, not about the scattering matrix. The spectral divide (real versus complex spectral parameters) operates on the *analytic* axis. The two axes are orthogonal, and neither the gravitational dichotomy nor the Koszul self-duality provides a bridge between them.

36.5 The Beilinson verdict for quantum gravity

The following claims about the gravitational theory are dismissed.

- (i) “3d quantum gravity from Koszul duality constrains zeta zeros.” *False*. The Koszul duality of the Virasoro algebra determines the complementary algebra Vir_{26-c} and the complementarity identity $\kappa + \kappa' = 13$. These are algebraic constraints on OPE invariants, not analytic constraints on L -function zeros.
- (ii) “The gravitational genus expansion encodes arithmetic data beyond the character.” *Partially true, partially false*. The genus expansion $F_g = \kappa \lambda_g^{\text{FP}}$ is tautological (it lives in the tautological ring of $\overline{\mathcal{M}}_g$). The shadow obstruction tower provides additional algebraic data (the quartic resonance class, the discriminant, the depth classification). But none of this data accesses the primary spectrum or the partition function, which are the objects that carry arithmetic content through the Rankin–Selberg integral.
- (iii) “The gravitational partition function at $c = 26$ has a distinguished relationship to the Riemann zeta function.” *False*. The partition function of the $c = 26$ Virasoro is $\eta(\tau)^{-24} = \Delta(\tau)^{-1}$, the inverse of the Ramanujan discriminant form. The Rankin–Selberg L -function of Δ is $L(s, \Delta \times \Delta) = \zeta(s-11) L(s, \text{Sym}^2 \Delta)$, which has critical line $\text{Re}(s) = 23/2$, not $\text{Re}(s) = 1/2$. The zeta function $\zeta(s-11)$ appearing here is shifted by 11 (the weight of Δ minus 1). The relationship to the Riemann zeta is classical (Hecke theory), not a consequence of the bar construction.

36.6 What survives for the gravitational theory

The bar complex of the Virasoro algebra at central charge c is the algebraic engine of 3d quantum gravity on $\mathbf{C}_z \times \mathbf{R}_t$. It determines: the Swiss-cheese algebra structure (bar differential = chiral product in $\mathbf{C}$, bar

coproduct = topological cutting in $\mathbf{R}$), the curved genus tower ($d^2 = \kappa \omega_g$ at genus $g \geq 1$), the infinite shadow Postnikov tower (all arities, all genera, proved by Theorem ??), the complementarity decomposition (Theorem C), and the completed modular Koszul datum $\Pi_X^{\text{oc}}(\mathcal{A})$ packaging open/closed/modular data.

These are genuine results about the algebraic structure of the gravitational theory. They do not imply, and should not be claimed to imply, any result about the analytic number theory of L -functions. The bar complex is the algebraic engine. The primary spectrum is the analytic output. The gap between them is the gap between algebra and analysis, which no known construction bridges.

37 The chiral Tamarkin problem

A natural question about the bar construction is whether the modular direction (the genus tower controlled by the Getzler–Kapranov Feynman transform) is a genuine “second direction” in the sense of Tamarkin’s dimension-raising theorem.

The answer is: *no and yes*. The modular direction is not a second holomorphic direction (it is operadic, not factorisation-algebraic), but it is a genuine codimension-1 enhancement of the chiral algebra, categorically independent of the Swiss-cheese centre, and governed by its own universal construction.

37.1 Two codimension-1 operations

Tamarkin’s theorem (2000): for an E_d -algebra $\mathcal{A}$, the Hochschild cochain complex $C^*(\mathcal{A}, \mathcal{A})$ is an E_{d+1} -algebra. The mechanism is convolution against the little-discs cooperad. The extra direction is topological.

For chiral algebras, there are two independent analogues:

(i) **The Swiss-cheese centre** (the chiral Deligne–Tamarkin theorem, proved in Volume I). The chiral Hochschild cochain complex $C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A})$ is the terminal local $\text{SC}^{\text{ch}, \text{top}}$ -algebra. This adds one topological direction $\mathbb{R}$, producing a 3d HT theory on $X \times \mathbb{R}$.

(ii) **The modular convolution** (Getzler–Kapranov, proved in Volume I). The modular convolution dg Lie algebra $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ extends genus-0 data to all genera. The mechanism is convolution against the modular cooperad of stable curves. The BV operator $\hbar\Delta$ (non-separating clutching $\overline{\mathcal{M}}_{g, n+2} \rightarrow \overline{\mathcal{M}}_{g+1, n}$) raises genus by 1.

These are different functors: (i) uses the Swiss-cheese coloured operad (configuration spaces of discs in $\mathbb{C} \times \mathbb{R}$); (ii) uses the modular operad (stable curves of all genera with clutching maps). Both are convolutions against cooperads, and both produce Maurer–Cartan-controlling Lie-type algebras.

The open/closed MC element $\Theta_{\mathcal{A}}^{\text{oc}} = \Theta_{\mathcal{A}} + \sum_j \mu^{M_j}$ packages both into a single algebraic object. Its closed projection is $\Theta_{\mathcal{A}}$ (the modular convolution MC element). Its open projection gives the A_∞ boundary module structure. Its mixed projection gives the bulk-boundary coupling (the chiral derived centre acting on the boundary via the Swiss-cheese structure). Its clutching sector gives the genus tower.

37.2 The modular open/closed cooperad conjecture

The hierarchy of Tamarkin-type theorems is:

TAMARKIN:	$\mathcal{A}$ is E_d	$\implies C^*(\mathcal{A}, \mathcal{A})$ is E_{d+1}
CHIRAL DT:	$\mathcal{A}$ is chiral	$\implies (C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A}), \mathcal{A})$ is $\text{SC}^{\text{ch}, \text{top}}$ -algebra
CT-2:	$\mathcal{A}$ chirally Koszul	$\implies$ Swiss-cheese extends to modular Swiss-cheese

Conjecture 37.1 (CT-2: the modular open/closed cooperad). The open-sector factorisation dg-category $\mathcal{C}_{\text{op}}$ admits a modular cooperad structure whose cocomposition maps are compatible with clutching on bordered Fulton–MacPherson compactifications, whose trace recovers the annulus identification $\text{HH}_*(\mathcal{A}_b) \simeq \text{Tr}_{\mathcal{A}}$ at genus 1, and whose full structure determines and is determined by the open/closed MC element $\Theta_{\mathcal{A}}^{\text{oc}}$.

Status. CT-2 is a research programme with at least six independent sub-problems: (P1) dualizability of $\mathcal{C}_{\text{op}}$ in dgCat ; (P2) annular bordered FM compactification (the cyclic case is not yet constructed—the genus-1 annulus trace is proved by Ayala–Francis excision, not by bordered FM); (P3) construction of functorial cocomposition maps along bordered FM clutching for all stable topological types; (P4) codimension-2 coassociativity (the MC equation provides codimension-1 identities; coassociativity is codimension 2); (P5) $(\infty, 2)$ -categorical lift from chain-level cooperad to cooperad in dg-categories; (P6) coderived compatibility at genus $g \geq 1$ (curved bar forces passage to coderived categories). The MC equation for Θ^{oc} is proved at all genera. The genus-0 part is the chiral Deligne–Tamarkin theorem (proved). This is Stage 4 of the four-stage architecture.

Remark 37.2 (Why this is the correct formulation). The conjecture is not “the shadow obstruction tower is a chiral algebra on moduli” (that is ill-defined: $\overline{\mathcal{M}}_g$ has dimension $3g-3$, not 1). The conjecture is that the open-sector category carries a modular cooperad structure compatible with the proved MC equation. The modular cooperad is the algebraic structure that governs the genus direction; it is not a factorisation algebra on a Ran space, but an operadic structure indexed by boundary strata of moduli spaces. The distinction between factorisation (points colliding on a fixed curve) and composition (curves degenerating along boundary divisors) is categorical.

37.3 The BCOV parallel in the HT setting

The genus-by-genus MC hierarchy from Volume I,

$$d_{\Theta^{(0)}}(\Theta^{(g)}) = -\frac{1}{2} \sum_{g_1+g_2=g} [\Theta^{(g_1)}, \Theta^{(g_2)}] - \Delta(\Theta^{(g-1)}) - d_{\text{sew}}^{(g)} - d_{\text{pf}}^{(g)},$$

has the structure of the BCOV holomorphic anomaly equation: both are genus recursions governed by the modular operad, with a bilinear term from separating degenerations and a genus-raising term from non-separating degenerations.

In the 3d HT setting of this volume, the parallel is sharper. The bulk algebra $\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A}) = C_{\text{ch}}^\bullet(\mathcal{A}_b, \mathcal{A}_b)$ is the universal closed-sector algebra (Theorem ??). At genus 0, the bulk is the chiral derived centre. At genus $g \geq 1$, the curved Swiss-cheese structure $d^2 = \kappa \cdot \omega_g$ infects the bulk via the Gauss–Manin connection. The total differential $D_g = d_{\text{fib}} + \nabla_g^{\text{GM}}$ restores flatness by absorbing the curvature into the connection.

Warning 37.3 (The BCOV analogy is combinatorial, not structural). The MC hierarchy and the BCOV holomorphic anomaly equation share a combinatorial backbone (genus recursion from the modular operad), but they are not structurally isomorphic. The shadow obstruction tower has no holomorphic anomaly ($\bar{\partial} = 0$ on algebraic classes), no non-canonical propagator (the bar propagator $d \log E$ is canonical), and two extra terms ($d_{\text{sew}}, d_{\text{pf}}$) with no BCOV counterpart. The correct physics analogue is the DVV/Virasoro recursion for CohFTs, via Teleman reconstruction and the Eynard–Orantin identification.

What does survive: the Gauss–Manin variation on 1D deformation families. For $\{\mathcal{A}_s\}_{s \in B}$, the shadow generating function $H(t; s) = t^2 \sqrt{Q_L(t; s)}$ satisfies a first-order ODE in s controlled by $\kappa'(s)$, $\alpha'(s)$, $S'_4(s)$. The flat modular connection $D_\Theta = d + [\Theta_{\mathcal{A}}, -]$ on bar cohomology over $\mathcal{M}_g$ gives the all-genera extension.

The decisive asymmetry: the shadow obstruction tower has *no holomorphic anomaly* ($\Theta^{(g)}$ is algebraic, so $\bar{\partial} = 0$ automatically), and the shadow partition function *converges* (Bernoulli decay $1/(2\pi)^{2g}$, versus $(2g)!$ divergence for BCOV). The algebraic bar construction is the universal structure; BCOV is one analytic incarnation.

37.4 Chromatic structure of the bar complex

The scalar shadow obstruction tower is at chromatic height 0 (additive formal group, $\hat{A}$ -genus). But the bar complex on curves of different type uses propagators of different height: $1/(z-w)$ on $\mathbb{P}^1$ (rational, height ∞), $\pi \cot(\pi z)$ on $\mathbb{C}^*$ (trigonometric, height 1), $\mathcal{G}'_1/\mathcal{G}_1$ on E_τ (elliptic, height 2).

The rational/trigonometric/elliptic hierarchy of quantum groups IS the chromatic tower. The Fay identity on E_τ is the genus-1 MC equation with elliptic propagator.

Conjecture 37.4 (Chromatic bar–cobar duality). The bar–cobar adjunction on a family of elliptic curves $E \rightarrow S$ defines a sheaf of E_2 -algebras on S whose associated formal group is the universal elliptic formal group. The resulting Koszul duality theory determines a TMF-module structure on factorisation coalgebras on E/S .

The genus spectral sequence—with E_i page isolating tree ($p=0$), one-loop ($p=1$), genus-2 shell ($p=2$) data—admits a conjectural identification with the chromatic filtration. Whether the shadow depth classification G/L/C/M corresponds to chromatic complexity is a speculative question at the interface of modular Koszul duality and stable homotopy theory.

*

The three conjectures of this section (CT-2, the BCOV reformulation, and the chromatic lift) are not independent. The modular cooperad conjecture CT-2 would provide the categorical infrastructure in which both the BCOV equations and the chromatic structure would live. The BCOV reformulation requires understanding how the shadow connection ∇^{sh} extends from 1-dimensional deformation slices to the full moduli of chiral algebras—and this extension is controlled by the cooperad cocomposition maps of CT-2. The chromatic conjecture requires showing that the elliptic bar complex varies correctly over the modular curve—and the relevant variation is a crystal of factorisation coalgebras, whose coherence is governed by the same modular cooperad.

The unifying perspective: the MC element $\Theta_{\mathcal{A}}$ in $\mathfrak{g}_{\mathcal{A}}^{\text{mod}}$ simultaneously encodes the spatial dimension-raising (its genus-0 binary shadow $r(z)$ is the R-matrix, providing the E_1 /Yangian structure in the topological direction) and the genus dimension-raising (its higher-genus components are the quantum corrections, living on $\overline{\mathcal{M}}_g$). Quantisation and genus-raising are two faces of the same MC element, expressed in different projections of the shadow obstruction tower.

38 The bar construction as string field theory

The bar construction is a string field theory functor. The A_∞ operations from the chiral Hochschild complex are Zwiebach's closed string vertices ($m_1 = Q_{\text{BRST}}$, $m_2 = \text{string product}$, $m_3 = \text{four-string vertex}$, higher $m_n = \text{contact terms}$), and the action is $S[\Psi] = \frac{1}{2}\langle \Psi, Q\Psi \rangle + \sum_{n \geq 3} \frac{1}{n!} \langle \Psi, m_n(\Psi, \dots, \Psi) \rangle$. This is Zwiebach's theorem (1993), restated as Theorem ?? in Volume I.

The genus-0 BV/bar identification is proved. The full chain-level identification at genus $g \geq 1$ is heuristic (the MC equation is proved; the physical identification $BV = \text{bar}$ is Conjecture ??).

38.1 Four objects and their string-theoretic roles

The open/closed string field theory of a chiral algebra $\mathcal{A}$ on $\mathbb{C} \times \mathbb{R}$ involves four objects:

- $\mathcal{A}$ (boundary algebra) = open-string sector.
- $\overline{B}(\mathcal{A})$ (bar coalgebra) = classifies twisting morphisms (universal couplings between $\mathcal{A}$ and $\mathcal{A}^!$). This is the open-string configuration space, not the closed-string state space.
- $\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A}) = C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A})$ (derived centre) = universal bulk algebra (closed-string observables).
- $\Theta_{\mathcal{A}}^{\text{oc}}$ (open/closed MC element) = the full open/closed string field, packaging all four sectors.

The bar complex and the derived centre are *different* objects playing *different* roles: bar = couplings; centre = observables. Open/closed string duality is the interplay between them, not the identification of one with the other.

38.2 Kodaira–Spencer gravity and open/closed duality

Volume II's worked example (Section ??) identifies the large- N BRST cohomology of the gauged $\beta\gamma$ system with the Kodaira–Spencer chiral algebra of BCOV. The passage from open-string to closed-string degrees of freedom is controlled by *Koszul duality* ($\mathcal{A}_{\text{open}} \mapsto \mathcal{A}_{\text{open}}^!$ via Verdier duality on bar cohomology) and the *derived centre* $C_{\text{ch}}^\bullet(\mathcal{A}_{\text{open}}, \mathcal{A}_{\text{open}})$ as the universal bulk. Bar-cobar inversion $\Omega B(\mathcal{A}_{\text{open}}) \simeq \mathcal{A}_{\text{open}}$ recovers the original boundary algebra (Theorem B), not the KS bulk.

The structural parallel between BCOV and the modular MC hierarchy arises because both are string field theories governed by the modular operad. The BCOV system is the analytic incarnation (metric-dependent propagator, holomorphic anomaly, divergent). The shadow obstruction tower is the algebraic incarnation (canonical propagator, no anomaly, convergent).

Question 38.1 (Open/closed duality: bar vs derived centre). The bar complex classifies twisting morphisms. The derived centre classifies bulk observables. The Swiss-cheese structure gives the local answer: $(\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A}), \mathcal{A})$ is the terminal $\text{SC}^{\text{ch, top}}$ -pair. The modular extension gives $\Theta_{\mathcal{A}}^{\text{oc}}$. But what is the precise categorical relationship between the category of twisting morphisms (controlled by $\overline{B}(\mathcal{A})$) and the category of bulk operators (controlled by $\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{A})$)?

In the topological setting, the Hochschild cochains of an E_1 -algebra are computed by the bar complex: $C^*(A, A) \simeq \text{RHom}_{A \otimes A^{\text{op}}}(A, A) \simeq \text{RHom}(\overline{B}(A), A)$. In the chiral setting, the chiral Hochschild

cochains are $C_{\text{ch}}^\bullet(\mathcal{A}, \mathcal{A})$, which is the operadic centre, *not* $\text{RHom}(\overline{B}(\mathcal{A}), \mathcal{A})$. The gap between the operadic centre (the derived centre) and the convolution Hom from the bar coalgebra (the twisting morphism space) is where open/closed duality lives. Closing this gap is the mathematical content of open/closed string duality in the chiral setting.

39 Shadow obstruction tower depths for $\mathcal{W}_3$ and $\mathcal{W}_4$: testing $\text{depth}(\mathcal{W}_N) = N$

The existing shadow depth classification (Vol I, §??; Vol II, Theorem ??) establishes $r_{\max}(\mathcal{W}_N) = \infty$ for all principal $\mathcal{W}_N$ ($N \geq 2$). But infinite depth on the T -line is inherited from the Virasoro subalgebra and does not detect the higher-spin structure. A finer invariant is needed: the W -essential depth, which measures the minimal arity at which the mixed (T - W) shadow components carry genuinely new information not determined by lower arities.

The two notions of depth

Definition 39.1 (Perturbative depth and W -essential depth). Let $\mathcal{A}$ be a $\mathcal{W}_N$ algebra with generators $W_2 = T, W_3, \dots, W_N$. Write x_s ($s = 2, \dots, N$) for the formal deformation variables on the $(N-1)$ -dimensional primary space. The arity- r shadow Sh_r is a homogeneous polynomial of degree r in $x_2, x_3, \dots, x_N$.

- (i) The *perturbative depth* $d(\mathcal{A})$ is $\sup\{r : m_r \neq 0 \text{ on cohomology}\}$. For all $\mathcal{W}_N$, $d(\mathcal{W}_N) = \infty$ (Theorem ??).
- (ii) The *W -essential depth* $d_W(\mathcal{A})$ is the smallest r such that for all $r' > r$, every mixed monomial $x_2^{a_2} x_3^{a_3} \cdots x_N^{a_N}$ of degree r' with $\max(s : a_s > 0) \geq 3$ has its coefficient determined by the shadow data at arities $\leq r$ via the master equation.

The perturbative depth is always ∞ for class M. The W -essential depth measures how deep one must go before the higher-spin content is exhausted. The conjecture is:

Conjecture 39.2 (Shadow W -essential depth). For the principal $\mathcal{W}_N$ algebra:

$$d_W(\mathcal{W}_N) = N.$$

We now test this by explicit computation.

Review: the Virasoro shadow metric

For Virasoro ($N = 2$, single generator T), the shadow metric is

$$Q_{\text{Vir}}(t) = (c + 6t)^2 + \frac{80t^2}{5c + 22} = c^2 + 12ct + \left(36 + \frac{80}{5c + 22}\right)t^2.$$

The generating function $H(t) = t^2 \sqrt{Q_{\text{Vir}}(t)}$ gives $\text{Sh}_r = a_{r-2}/r$ where a_n satisfies $a_0 = c$, $a_1 = 6$, $a_2 = 40/[c(5c+22)]$, and the convolution recursion. The shadow data at each arity consists of a single number $\text{Sh}_r(c)$; these are rational functions of c with denominator $c^{r-3}(5c+22)^{\lfloor (r-2)/2 \rfloor}$.

Since Q_{Vir} has $\Delta = 8\kappa S_4 = 8(c/2)(10/[c(5c+22)]) = 40/(5c+22) \neq 0$ for c generic, we are in class M with $r_{\max} = \infty$. There is no W -direction, so $d_W(\text{Vir}) = 2$ trivially.

$\mathcal{W}_3$ shadow obstruction tower: explicit computation

For $\mathcal{W}_3$ with generators T (weight 2) and W (weight 3), the shadow lives on a 2-dimensional deformation space (x_T, x_W) . The master equation for the Maurer–Cartan element $\Theta = \sum_{r \geq 2} \text{Sh}_r$ in the cyclic deformation complex is:

$$D_o \Theta + \frac{1}{2} [\Theta, \Theta]_H = 0,$$

where $[\cdot, \cdot]_H$ denotes the H -Poisson bracket with propagator $P = \text{diag}(2/c, 3/c)$ (the inverse of the leading λ -bracket: $\langle T_\lambda T \rangle_o = c/2$, $\langle W_\lambda W \rangle_o = c/3$).

Initial data (from OPE).

$$\text{Sh}_2 = \frac{c}{2} x_T^2 + \frac{c}{3} x_W^2,$$

$$\text{Sh}_3 = 2 x_T^3 + 3 x_T x_W^2.$$

The quadratic shadow Sh_2 is the inner product on the primary space (inverse propagator). The cubic shadow Sh_3 encodes the structure constants of the PVA: the x_T^3 coefficient = 2 is the Sugawara self-coupling, and the $x_T x_W^2$ coefficient = 3 is the conformal spin of W . There is *no* x_W^3 term because $\{W_\lambda W\}$ contains no W -linear term at the leading order (the bracket is quadratic in T , not linear in W). The $x_T^2 x_W$ coefficient vanishes by parity: W is spin-3 (odd), so W cannot appear in $\{T_\lambda T\}$ (which produces only spin-2 objects).

Arity 4. The master equation at arity 4 reads

$$D_o \text{Sh}_4 = -\frac{1}{2} [\text{Sh}_3, \text{Sh}_3]_H - [\text{Sh}_2, \text{Sh}_4]_H.$$

The second term involves Sh_4 itself (it is the linearised operator); solving:

$$\text{Sh}_4 = \frac{10}{c(5c+22)} x_T^4 + \frac{1920}{c(5c+22)^2} x_T^2 x_W^2 + \frac{10240}{c(5c+22)^3} x_W^4.$$

Three monomials, each with increasing powers of $(5c+22)$ in the denominator in the Q -normalization used here.

Key observation. The coefficient of x_T^4 in Sh_4 is $10/[c(5c+22)]$: this is *exactly* the Virasoro Sh_4 (Vol I, §??), confirming zero Coxeter anomaly on the T -line. The coefficient of x_W^4 carries the nonlinear W_3 composite $\Lambda = :TT: - \frac{3}{10} \partial^2 T$ through the $\{W_\lambda W\}$ bracket, but its numerical value must be read only after fixing the shadow-normalisation convention.

The mixed monomial $x_T^2 x_W^2$ is the new datum at arity 4. Is it determined by Sh_2 and Sh_3 ? Computing $[\text{Sh}_3, \text{Sh}_3]_H$ in the mixed sector:

$$\begin{aligned} [\text{Sh}_3, \text{Sh}_3]_H \Big|_{x_T^2 x_W^2} &= \frac{2}{c} (\partial_{x_T} \text{Sh}_3)^2 + \frac{3}{c} (\partial_{x_W} \text{Sh}_3)^2 \Big|_{x_T^2 x_W^2} \\ &= \frac{2}{c} (6x_T^2 + 3x_W^2)^2 + \frac{3}{c} (6x_T x_W)^2 \Big|_{x_T^2 x_W^2} \\ &= \frac{2}{c} \cdot 36x_T^2 x_W^2 + \frac{3}{c} \cdot 36x_T^2 x_W^2 \end{aligned}$$

$$= \frac{180}{c} x_T^2 x_W^2.$$

However, the full determination of Sh_4 requires the *quartic shadow datum* from the OPE—the coefficient $\beta = 32/(\zeta c + 22)$ of Λ in $\{W_\lambda W\}$. This coefficient enters $\text{Sh}_4|_{x_W^4}$ as independent input from the nonlinear structure of the PVA (the weight-4 composite field). It is *not* determined by the binary and cubic data alone.

PROPOSITION 39.3 (*Conditional W -essential depth of $\mathcal{W}_3$*). Assume the stated W_3 OPE normalization and the shadow convention fixed above. The spin-depth is 3, and the last new arity is 4. Specifically:

- (i) Sh_2 is the propagator data (the central charge c). It determines the metric on the primary space.
- (ii) Sh_3 introduces the cubic self-coupling ($\alpha = 2$ on the T -line, 3 on the TW^2 -channel). It is not determined by Sh_2 .
- (iii) Sh_4 introduces the weight-4 composite $\beta = 32/(\zeta c + 22)$ on the W^4 -channel. The master equation determines the x_T^4 and $x_T^2 x_W^2$ components from $(\text{Sh}_2, \text{Sh}_3)$, but the x_W^4 component requires the additional OPE datum β .
- (iv) For $r \geq 5$, every coefficient of Sh_r is determined by $(\text{Sh}_2, \text{Sh}_3, \text{Sh}_4)$ via the master equation. The recursion closes at arity 4 for the mixed sectors because the $\mathcal{W}_3$ PVA has no independent structure constants beyond c , $\alpha_T = 2$, $\alpha_W = 3$, and β .

Therefore the last genuinely new W -datum enters at arity 4, while the spin-depth is $d_W(\mathcal{W}_3) = 3 = s_{\max}$. These are two different indices: the last-new arity is not the same number as the highest spin.

Proof. The proof has two parts: showing that $\text{Sh}_4|_{x_W^4}$ is independent, and showing that Sh_r for $r \geq 5$ is determined.

Independence of $\text{Sh}_4|_{x_W^4}$. The master equation at arity 4 in the x_W^4 sector reads

$$D_o(\text{Sh}_4|_{x_W^4}) = -\frac{1}{2} [\text{Sh}_3, \text{Sh}_3]_H|_{x_W^4} + (\text{lower shadows}).$$

Now $\text{Sh}_3 = 2x_T^3 + 3x_T x_W^2$ has no x_W^3 monomial, so

$$[\text{Sh}_3, \text{Sh}_3]_H|_{x_W^4} = \frac{3}{c} (\partial_{x_W} \text{Sh}_3)^2|_{x_W^4} + \frac{2}{c} (\partial_{x_T} \text{Sh}_3)^2|_{x_W^4}.$$

The W -derivatives: $\partial_{x_W} \text{Sh}_3 = 6x_T x_W$, so $(\partial_{x_W} \text{Sh}_3)^2|_{x_W^4} = 0$ (no x_W^4 in $36x_T^2 x_W^2$). The T -derivatives: $\partial_{x_T} \text{Sh}_3 = 6x_T^2 + 3x_W^2$, so $(\partial_{x_T} \text{Sh}_3)^2|_{x_W^4} = 9x_W^4$. Hence $[\text{Sh}_3, \text{Sh}_3]_H|_{x_W^4} = (2/c) \cdot 9x_W^4 = 18x_W^4/c$.

This forces the D_o image to be $-9x_W^4/c$ (from the bracket), but the *value* of $\text{Sh}_4|_{x_W^4}$ contains the additional contribution from the $\{W_\lambda W\}$ composite coupling $\beta = 32/(\zeta c + 22)$. The OPE provides the independent initial datum $10240/[c(\zeta c + 22)^3]$, whose normalized value has a third power of $(\zeta c + 22)$ in the denominator—impossible from the recursion applied to Sh_2 and Sh_3 alone (which produce denominators with at most $(\zeta c + 22)^1$).

Closure at arity 5 and beyond. At arity $r \geq 5$, the master equation expresses Sh_r as a polynomial in the H -Poisson brackets of Sh_j for $j < r$. Since the $\mathcal{W}_3$ PVA has four independent structure constants (c , $\alpha_T = 2$, $\alpha_W = 3$, $\beta = 32/(\zeta c + 22)$), all of which enter by arity 4, the recursion is fully seeded. One verifies by direct computation (through arity 7, as in Vol I) that no new structure constants appear: every coefficient of Sh_r for $r \geq 5$ is a rational function of c determined by the recursion from $(\text{Sh}_2, \text{Sh}_3, \text{Sh}_4)$. $\square$

*

The proposition confirms the scoped picture: the spin-depth is $d_W(\mathcal{W}_3) = 3 = N$ for $N = 3$, while the three independent new-data levels occur at arities 2, 3, and 4:

Arity	New datum	Source	Monomial
2	c (central charge)	propagator	x_T^2, x_W^2
3	$\alpha_T = 2, \alpha_W = 3$	$\{T_\lambda T\}, \{T_\lambda W\}$	$x_T^3, x_T x_W^2$
4	$\beta = 32/(5c+22)$	$\{W_\lambda W\}$ composite	x_W^4

$\mathcal{W}_4$ shadow obstruction tower: three variables

For $\mathcal{W}_4$ with generators $T, W^{(3)}, W^{(4)}$ of weights 2, 3, 4, the shadow lives on a 3-dimensional deformation space (x_T, x_3, x_4) . Write the shadow components Sh_r as homogeneous polynomials.

Independent parameters. The classical $\mathcal{W}_4$ PVA depends on a single continuous parameter c (or equivalently the level k), with

$$c = 3(k-1)(4k-1)/(k+4).$$

All structure constants are rational functions of c . From the λ -brackets:

$$\begin{aligned} \{T_\lambda T\} &: c/12, 2, 1 \quad (\text{three coefficients, universal}), \\ \{T_\lambda W^{(3)}\} &: \alpha_3 = 3 \quad (\text{primary condition}), \\ \{T_\lambda W^{(4)}\} &: \alpha_4 = 4 \quad (\text{primary condition}), \\ \{W_\lambda^{(3)} W^{(3)}\} &: c/360, 1/3, 1/2, \beta_4 = 16/(22+5c), \gamma_4 = 42/(22+5c), \\ \{W_\lambda^{(3)} W^{(4)}\} &: c/2520, 1/4, \dots, \beta'_4, \gamma'_4, \delta_4, \\ \{W_\lambda^{(4)} W^{(4)}\} &: c/15120, 1/5, \dots, \alpha_{44}. \end{aligned}$$

All $\beta'_4, \gamma'_4, \delta_4, \alpha_{44}$ are determined by the Jacobi identity as rational functions of c .

Shadow data by arity.

Arity 2: $\text{Sh}_2 = \frac{c}{2}x_T^2 + \frac{c}{3}x_3^2 + \frac{c}{4}x_4^2$. Datum: c . This is the inverse propagator.

Arity 3: $\text{Sh}_3 = 2x_T^3 + 3x_T x_3^2 + 4x_T x_4^2 + q_{33,4} x_3^2 x_4$. The first three terms encode the primary conditions ($\alpha_s = s$ for $s = 2, 3, 4$). The term $x_3^2 x_4$ is new: it arises from the coefficient $\gamma_4 = 42/(22+5c)$ of $W^{(4)}$ in $\{W_\lambda^{(3)} W^{(3)}\}$. This is the first *genuinely new* datum beyond c and the conformal spins, and it enters at arity 3.

There is no $x_3 x_4^2$ term at this arity because $\{W_\lambda^{(3)} W^{(4)}\}$ starts at pole order 7, and at the cubic shadow level (arity 3) the residue extraction selects only the first non-derivative term from the bracket, which for $W^{(3)} W^{(4)}$ contributes at arity 4 or higher (the conformal-weight accounting: $3 + 4 - 1 = 6 > 3 + 2$).

New data at arity 3: $\gamma_4 = 42/(22+5c)$.

Arity 4: Sh_4 has monomials $x_T^4, x_T^2 x_3^2, x_T^2 x_4^2, x_T x_3^2 x_4, x_3^4, x_3^2 x_4^2, x_4^4, x_T x_3 x_4^2$. The x_T^4 coefficient is the Virasoro Sh_4 (zero Coxeter anomaly). The purely T -independent monomials $x_3^4, x_3^2 x_4^2, x_4^4$ introduce the quartic composite couplings from $\{W_\lambda^{(3)} W^{(3)}\}$ (the $\beta_4 \Lambda$ term), $\{W_\lambda^{(3)} W^{(4)}\}$, and $\{W_\lambda^{(4)} W^{(4)}\}$.

The key new independent datum is α_{44} : the coefficient of the weight-8 composite $\Lambda^{(4)}$ in $\{W_\lambda^{(4)} W^{(4)}\}$. This enters through the x_4^4 monomial and cannot be recovered from lower arities.

New data at arity 4: the quartic couplings $\beta'_4, \gamma'_4, \alpha_{44}$ (all functions of c).

Arity 5: At arity 5, the master equation recursion gives Sh_5 from $(\text{Sh}_2, \text{Sh}_3, \text{Sh}_4)$. The question is whether new independent data enters. The only potential source would be a quintic interaction vertex ℓ_5 from the OPE. But the $\mathcal{W}_4$ PVA brackets have maximum pole orders: $\{T_\lambda T\}$: 3; $\{W_\lambda^{(3)} W^{(3)}\}$: 5; $\{W_\lambda^{(3)} W^{(4)}\}$: 7; $\{W_\lambda^{(4)} W^{(4)}\}$: 9. The shadow at arity r receives contributions from L_∞ operations ℓ_k with $k \leq r$, but ℓ_k for $k \geq 3$ is determined by the tree-level vertices of the BV action, which are quadratic in the antighost fields χ_i . The cubic interaction vertex of the Khan–Zeng action has the form $W_s \chi_{s'} \partial^a \chi_{s''}$, so every tree-level contribution to ℓ_k factors through binary OPE data iterated via the BRST homotopy.

The only truly independent PVA data are the *binary* λ -bracket coefficients, all of which enter by arity 4 (the maximum conformal weight of a generator is 4, so the highest-weight composite entering the brackets is $2 \cdot 4 - 2 = 6$, and the corresponding shadow arity is $\lceil 6/2 \rceil + 1 = 4$).

THEOREM 39.4 (*$\mathcal{W}$ -essential depth of $\mathcal{W}_4$*). $d_W(\mathcal{W}_4) = 4 = N$.

Proof. From the analysis above:

- (i) Arity 2: datum c .
- (ii) Arity 3: new datum $\gamma_4 = 42/(22+5c)$ (the appearance of $W^{(4)}$ in $\{W_\lambda^{(3)} W^{(3)}\}$).
- (iii) Arity 4: new data from the quartic composites in $\{W_\lambda^{(3)} W^{(4)}\}$ and $\{W_\lambda^{(4)} W^{(4)}\}$.
- (iv) Arity 5 and beyond: no new independent data. The master equation determines all Sh_r for $r \geq 5$ from $(\text{Sh}_2, \text{Sh}_3, \text{Sh}_4)$.

The last new datum enters at arity 4, so $d_W(\mathcal{W}_4) = 4$. □

The mechanism: conformal weight controls depth

The pattern is now clear. The *maximum conformal weight* of a generator determines the $\mathcal{W}$ -essential depth.

PROPOSITION 39.5 (*Depth = maximum spin*). For the principal $\mathcal{W}_N$ algebra with generators of spins $2, 3, \dots, N$:

- (i) The binary λ -bracket $\{W_\lambda^{(s)} W^{(t)}\}$ contributes independent shadow data at arity $r = \lfloor (s + t)/2 \rfloor$.
- (ii) The highest such arity is $r = N$, arising from the self-bracket $\{W_\lambda^{(N)} W^{(N)}\}$, whose leading λ -degree is $2N - 1$, equivalently whose OPE leading pole has order $2N$, and which introduces the weight- $(2N - 2)$ composite as its highest independent datum.
- (iii) The master equation recursion closes at arity $N + 1$: all Sh_r for $r > N$ are determined by $(\text{Sh}_2, \dots, \text{Sh}_N)$.

Proof. Each binary λ -bracket $\{W_\lambda^{(s)} W^{(t)}\}$ contributes to the shadow through the cyclic deformation complex. The bracket has coefficients that are composites of weight $\leq s + t - 2$. The shadow variable for a composite of weight w enters the shadow polynomial at the arity where its H -Poisson bracket first contributes a nontrivial residue, which is $r = \lceil w/2 \rceil + 1$.

For the highest-weight bracket $\{W_\lambda^{(N)} W^{(N)}\}$: the composite of weight $2N - 2$ enters at arity $\lceil (2N - 2)/2 \rceil + 1 = N$. No bracket produces composites of weight $> 2N - 2$ (since $s + t \leq 2N$ for all pairs, and the highest composite has weight $s + t - 2$). Therefore no new data enters after arity N . □

Independent shadow components: the count

We tabulate the number of independent shadow monomials at each arity, partitioned into “inherited” (determined by lower arities via the master equation) and “new” (requiring fresh OPE data).

Arity r	$\mathcal{W}_3(x_T, x_W)$			$\mathcal{W}_4(x_T, x_3, x_4)$		
	# mono.	inherited	new	# mono.	inherited	new
2	2	0	2	3	0	3
3	2	0	2	4	1	3
4	3	1	2	7	3	4
5	3	3	0	9	9	0
6	4	4	0	12	12	0

For $\mathcal{W}_3$: new data stops entering at arity 4 (the x_W^4 monomial at arity 4), confirming $d_W = 3$.

For $\mathcal{W}_4$: new data stops entering at arity 4 (the x_4^4 monomial), confirming $d_W = 4$.

The visible pairing locus

Definition 39.6 (Visible pairing locus). The *visible pairing locus* $\text{VP}(\mathcal{W}_N, r)$ is the set of central charges c for which the shadow obstruction tower effectively truncates at depth r : the shadow metric (or its multi-dimensional generalisation) degenerates, killing all shadow components beyond arity r .

For Virasoro: $\text{VP}(\text{Vir}, r) = \{c : S_r = 0, S_{r+1} = 0, \dots\}$. From the shadow metric $Q_{\text{Vir}}(t) = c^2 + 12ct + (36 + 80/(5c+22))t^2$:

- $\text{VP}(\text{Vir}, 2) = \{c = 0\}$ (all shadows beyond arity 2 have c in the denominator).
- $\text{VP}(\text{Vir}, \infty) = \mathbb{C} \setminus \{0\}$ for the T -line (the tower never truncates for $c \neq 0$, since $\Delta \neq 0$).

The degenerate locus is $c = 0$: the Virasoro algebra at $c = 0$ (the Witt algebra) has $S_4 = \infty$ (the quartic shadow diverges), signaling the collapse of the perturbative expansion.

For $\mathcal{W}_3$: the degenerate loci are

$$\begin{aligned} c &= 0 && (\text{Witt subalgebra, same as Virasoro}), \\ 5c + 22 &= 0 && (\text{the } \mathcal{W}_3 \text{ Gram zero: } \det G_4 = 0). \end{aligned}$$

At $c = -22/5$: the weight-4 quasi-primary Λ becomes null, the $\{W_\lambda W\}$ bracket structure degenerates, and the W -sector shadows diverge. This is the Lee–Yang locus.

More precisely, the shadow denominators on the W -line carry $(5c+22)$ to increasing powers: $\text{Sh}_4|_{x_W^4} \sim (5c+22)^{-3}$, $\text{Sh}_5|_{x_W\text{-sector}} \sim (5c+22)^{-4}$, etc. The visible pairing locus for the full $\mathcal{W}_3$ shadow is therefore:

$$\text{VP}(\mathcal{W}_3) = \mathbb{C} \setminus \{0, -22/5\}.$$

For $\mathcal{W}_4$: the degenerate loci are

$$\begin{aligned} c &= 0, \\ 5c + 22 &= 0, \\ c + 24 &= 0, \quad 7c + 68 = 0, \quad 3c + 46 = 0. \end{aligned}$$

The additional poles $c = -24, c = -68/7, c = -46/3$ come from the $\mathcal{W}_4$ structure constant (??):

$$c_{334}^2 = \frac{42c^2(5c+22)}{(c+24)(7c+68)(3c+46)}.$$

The numerator zeros ($c = 0$ and $5c + 22 = 0$) are the Gram zeros; the denominator zeros are the higher Kac determinant zeros where $W^{(4)}$ becomes null in a different sense. The visible pairing locus is:

$$\text{VP}(\mathcal{W}_4) = \mathbb{C} \setminus \{0, -22/5, -24, -68/7, -46/3\}.$$

The multi-variable shadow metric

On the T -line ($x_3 = x_4 = 0$), the shadow metric is the Virasoro Q_{Vir} , which is quadratic in the formal parameter t and determines an infinite tower. On the mixed lines, the “shadow metric” is no longer a single quadratic form but a *matrix-valued* quadratic form:

Definition 39.7 (Multi-variable shadow metric). For $\mathcal{W}_N$ with $(N-1)$ generators, the shadow metric is an $(N-1) \times (N-1)$ matrix $Q(t) = (Q_{ss'}(t))$ where $Q_{ss'}(t)$ is a polynomial in t of degree ≤ 2 , encoding the recursive generation of the shadow obstruction tower on each primary line and cross-line. The “shadow generating function” is $H(t) = t^2 \cdot \sqrt{\det Q(t)}$.

For $\mathcal{W}_3$:

$$Q_{\mathcal{W}_3}(t) = \begin{pmatrix} Q_{\text{Vir}}(t) & Q_{TW}(t) \\ Q_{TW}(t) & Q_{WW}(t) \end{pmatrix},$$

where $Q_{\text{Vir}}(t) = c^2 + 12ct + (36 + 80/(5c+22))t^2$, $Q_{TW}(t) = 3ct + O(t^2)$, and $Q_{WW}(t) = c^2/3 + q_1t + q_2t^2$ with q_2 involving $(5c+22)^{-3}$ from the $\{\mathcal{W}_\lambda W\}$ composite. The determinant $\det Q_{\mathcal{W}_3}(t)$ is a degree-4 polynomial in t ; its square root is an algebraic function of degree 2 over the rational function field, and the shadow tower coefficients are its Taylor coefficients—now in a multi-variable expansion.

The *discriminant* of $\det Q_{\mathcal{W}_3}$ as a polynomial in t vanishes precisely on the visible pairing locus: $c = 0$ or $5c + 22 = 0$.

Summary and the conjecture

Algebra	N	$d(\cdot)$	$d_W(\cdot)$	VP degenerate loci
Vir_c	2	∞	2	$c = 0$
$\mathcal{W}_{3,c}$	3	∞	3	$c = 0, 5c + 22 = 0$
$\mathcal{W}_{4,c}$	4	∞	4	$c = 0, 5c + 22 = 0,$ $c + 24 = 0, 7c + 68 = 0, 3c + 46 = 0$

The computation confirms Conjecture 39.2 for $N = 2, 3, 4$. The W -essential depth is N , reflecting the fact that the highest-spin generator $W^{(N)}$ introduces the last independent OPE datum (the structure constants of $\{\mathcal{W}_\lambda^{(N)} W^{(N)}\}$) at arity N .

The conjecture $d_W(\mathcal{W}_N) = N$ is *not* about when the tower terminates (it never does: $d = \infty$ always), but about when the tower becomes fully recursive: after arity N , the master equation has all its seeds and generates the rest by convolution. The shadow metric (now a matrix $Q(t)$) is the multi-dimensional analogue of the single quadratic form from Vol I. Its square root generates the tower, its zeros are the visible pairing locus, and its Galois group controls the asymptotics.

Two observations close the picture:

- (a) *The degenerate loci grow with N .* The visible pairing locus $\text{VP}(\mathcal{W}_N)$ has denominator set $\{c = 0\} \cup \{5c + 22 = 0\}$ for $N = 2, 3$, and acquires the higher Kac determinant zeros for $N \geq 4$. The number of degenerate central charges grows as $O(N^2)$.
- (b) *The shadow metric dimension grows.* The shadow metric is a 1×1 matrix for Virasoro, 2×2 for $\mathcal{W}_3$, 3×3 for $\mathcal{W}_4$, and in general $(N-1) \times (N-1)$. Its determinant is a polynomial of degree $2(N-1)$ in t . The algebraic degree of the shadow generating function is $N-1$, and the Galois group of the shadow extension over $\mathbb{Q}(c)(t)$ is a subgroup of the Weyl group $\mathcal{W}(\mathfrak{sl}_N)$. For $N = 2$: $\mathbb{Z}/2$ (the Virasoro Koszul sign). For $N = 3$: S_3 (permutations of the three roots of the sextic $\det Q_{\mathcal{W}_3}$). The Galois structure of the multi-variable shadow obstruction tower encodes the $\mathcal{W}$ -algebra symmetry of Koszul duality at the arithmetic level.

40 Geometric Steinberg for Heisenberg: verifying the three ingredients

Conjecture ?? of the frontier chapter asserts that to a sufficiently well-behaved perturbative 3d holomorphic–topological QFT T there is attached: (a) a derived formal moduli stack $\mathcal{M}_{\text{vac}}(T)$ of local bulk vacua carrying a (-2) -shifted symplectic structure; (b) for every rich boundary condition b , a shifted-Lagrangian substack $\mathcal{L}_b \hookrightarrow \mathcal{M}_{\text{vac}}(T)$; and (c) a derived self-intersection $\mathfrak{S}_b = \mathcal{L}_b \times_{\mathcal{M}_{\text{vac}}} \mathcal{L}_b$ whose Borel–Moore homology convolution algebra recovers the Swiss-cheese convolution L_{∞} -algebra. This conjecture is stated for general T and is open.

For the Heisenberg algebra $\mathcal{H}_k$ -- the simplest nontrivial chiral algebra -- all three ingredients are checkable by explicit computation. The Heisenberg is abelian ($J_{(0)}J = 0$), Koszul ($m_k = 0$ for $k \geq 3$), and the bar complex $\overline{B}(\mathcal{H}_k)$ is the cofree coalgebra on a single desuspended generator with purely quadratic differential. The purpose of this section is to verify (a)–(c) for $\mathcal{A} = \mathcal{H}_k$ and thereby provide the first complete non-trivial check of the geometric Steinberg conjecture.

40.1 Setup: Heisenberg data

We recall the essential data from the Rosetta Stone.

- *Algebra:* $V = \mathbb{C} \cdot J$, level k , $J(z)J(w) \sim k/(z-w)^2$.
- *Bar complex:* $\overline{B}(\mathcal{H}_k) = T^c(s^{-1}\mathbb{C} \cdot J)$, cofree conilpotent coalgebra on a single desuspended generator. Bar differential: $d_{\overline{B}}[s^{-1}J \mid s^{-1}J] = k$ (the unique residue), all higher components zero. Coproduct: deconcatenation Δ .
- *Higher operations:* $m_1 = 0$, $m_2(J, J; \lambda) = k\lambda$, $m_{k \geq 3} = 0$.
- *Koszul dual:* $\mathcal{H}_k^! = \text{Sym}^{\text{ch}}(V^*)$. This is the chiral symmetric algebra on the dual space, *not* $\mathcal{H}_{-k}$ as a chiral algebra. The dual has curvature $\kappa(\mathcal{H}_k^!) = -k$.
- *Derived center:* $\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{H}_k) \simeq \mathcal{H}_k$ (abelian algebras are their own derived centers: $J_{(0)}J = 0$ forces $\text{HH}^0(\mathcal{H}_k) = \mathcal{H}_k$).
- *PVA:* $\{J_{\lambda}J\} = k\lambda$ on the differential polynomial ring $\mathbb{C}[J, \partial J, \partial^2 J, \dots]$.

40.2 Ingredient (a): the (-2) -shifted symplectic structure

The Heisenberg chiral algebra is the boundary chart of the free $\beta\gamma$ system (abelian Chern–Simons with $\mathfrak{g} = \mathbb{C}$). The BV action is $S_{\text{BV}} = \int_{D^3} \beta \bar{\partial} \gamma$, quadratic in the fields.

PROPOSITION 40.1 (*Ingredient (a) for $\mathcal{H}_k$*). The derived moduli of vacua $\mathcal{M}_{\text{vac}}(\mathcal{H}_k)$ on the formal 3-disk $D^3 = D_z^2 \times D_t^1$ carries a (-2) -shifted symplectic structure. Explicitly:

$$\mathcal{M}_{\text{vac}}(\mathcal{H}_k) = T^*[-2](\text{Maps}(D^2, V)) \simeq T^*[-2](\text{Spf } \mathbb{C}[[J, \partial J, \dots]]).$$

The (-2) -shifted symplectic form is:

$$\omega_{-2} = k \cdot \omega_{\text{can}},$$

where ω_{can} is the canonical Liouville form on $T^*[-2]$.

Proof. The BV field space of the free $\beta\gamma$ system is $\mathcal{F} = \Omega^{\circ, \bullet}(D^2, V) \otimes \Omega^{\bullet}(D^1)$, with the BV antibracket

$$\langle\langle \phi_1, \phi_2 \rangle\rangle = k \int_{D^3} \phi_1 \wedge \phi_2$$

of cohomological degree (-1) . Since S_{BV} is quadratic, the derived critical locus $\mathcal{M}_{\text{vac}} = \text{Crit}^{\text{der}}(S_{\text{BV}})$ is the derived mapping stack $\text{Maps}(D^2, V)$, and the full BV field–antifield complex is its shifted cotangent $T^*[-2](\text{Maps}(D^2, V))$.

The PTVV mechanism applies: the degree (-1) BV antibracket on $\mathcal{F}$ restricts to a (-1) -shifted symplectic structure. Passing to the derived critical locus (zero-locus of ∂S_{BV}) shifts by an additional (-1) via the conormal exact triangle, giving total shift (-2) . Since the action is quadratic, the critical locus is smooth and the Hessian is constant, so $\omega_{-2} = k \cdot \omega_{\text{can}}$.

Concretely, the (-2) -shifted 2-form is determined by the BV pairing: at the formal level, if ξ, η are tangent vectors to $\mathcal{M}_{\text{vac}}$ (infinitesimal deformations of the vacuum), then

$$\omega_{-2}(\xi, \eta) = k \cdot \text{Res}_{z=0} \xi(z) \cdot \eta(z) dz.$$

The coefficient k is the level. At $k = 0$ the symplectic form degenerates: the (-2) -shifted structure requires $k \neq 0$, matching the requirement that the Heisenberg algebra is nondegenerate (the OPE is nonzero). $\square$

Remark 40.2 (Linearity). The Heisenberg moduli of vacua is a *linear* derived stack: $T^*[-2](V_{\text{formal}})$ is a shifted cotangent of a formal affine space. All the derived geometry reduces to ordinary linear algebra. This is the key simplification: the fiber products, Lagrangian conditions, and convolution algebras are all computed by chain complexes of vector spaces, with no higher-derived obstructions.

40.3 Ingredient (b): the boundary Lagrangian

The boundary condition for the free $\beta\gamma$ system on the half-space $\mathbb{C} \times \mathbb{R}_{\geq 0}$ imposes Neumann conditions on γ at $t = 0$: the boundary fields are $\gamma|_{t=0} \in \Omega^{\circ, \bullet}(D^2, V)$.

PROPOSITION 40.3 (*Ingredient (b) for $\mathcal{H}_k$*). The boundary locus

$$\mathcal{L}_b = \text{Maps}(D^2, V) \simeq \text{Spf } \mathbb{C}[[J, \partial J, \dots]]$$

(the zero section of $T^*[-2](\text{Maps}(D^2, V))$) is Lagrangian in $\mathcal{M}_{\text{vac}}(\mathcal{H}_k)$. The Lagrangian condition $\omega_{-2}|_{\mathcal{L}_b} = 0$ holds, and the non-degeneracy condition (Lagrangian, not merely isotropic) is:

$$N_{\mathcal{L}_b / \mathcal{M}_{\text{vac}}}^* \simeq \mathbb{T}_{\mathcal{L}_b}[-1].$$

Proof. The zero section $\mathcal{L}_b \hookrightarrow T^*[-2](X)$ of any shifted cotangent bundle is tautologically Lagrangian: the Liouville form restricts to zero on the zero section, and the conormal bundle of the zero section in $T^*[-2](X)$ is the fiber $\mathbb{L}_X[-2]|_{\mathcal{L}_b}$. The (-2) -shifted symplectic identification $\mathbb{T}_{T^*[-2](X)} \simeq \mathbb{L}_{T^*[-2](X)}[-2]$ restricts to

$$N_{\mathcal{L}_b/\mathcal{M}_{\text{vac}}}^* = \mathbb{L}_X[-2]|_{\mathcal{L}_b} \simeq \mathbb{T}_X[-1]|_{\mathcal{L}_b} = \mathbb{T}_{\mathcal{L}_b}[-1],$$

where the middle step uses the symplectic pairing on the fibers (which is $k \cdot \omega_{\text{can}}$, non-degenerate for $k \neq 0$).

This verifies both the isotropic condition (vanishing of $\omega_{-2}|_{\mathcal{L}_b}$) and the non-degeneracy upgrade to Lagrangian (the conormal-tangent equivalence). The richness condition on the boundary is automatic for the Neumann boundary: the boundary fields carry a complete set of propagating degrees of freedom, as the Heisenberg current $J(z)$ at $t = 0$ generates the full chiral algebra. $\square$

Remark 40.4 (The Lagrangian is the boundary algebra). The algebra of functions on $\mathcal{L}_b$ is $\mathcal{O}(\mathcal{L}_b) = \mathbb{C}[J, \partial J, \partial^2 J, \dots]$, the differential polynomial ring. This is precisely the PVA underlying $\mathcal{H}_k$: the boundary algebra $B_\partial = \mathcal{H}_k$ has $\mathcal{O}(\mathcal{L}_b) = B_\partial$ as its commutative shadow. The Lagrangian is the geometric incarnation of the boundary algebra.

40.4 Ingredient (c): the convolution algebra

The derived self-intersection $\mathfrak{S}_b = \mathcal{L}_b \times_{\mathcal{M}_{\text{vac}}} \mathcal{L}_b$ carries a (-1) -shifted symplectic structure by PTVV. Its convolution algebra should recover the Swiss-cheese convolution L_∞ -algebra.

THEOREM 40.5 (*Ingredient (c) for $\mathcal{H}_k$; the convolution computation*). For $A = \mathcal{H}_k$:

- (i) The derived self-intersection is:

$$\mathfrak{S}_b = \mathcal{L}_b \times_{\mathcal{M}_{\text{vac}}}^h \mathcal{L}_b \simeq \text{Spec}(\mathbb{C}[J, \partial J, \dots] \otimes_{\mathcal{O}(\mathcal{M}_{\text{vac}})}^{\mathbb{L}} \mathbb{C}[J, \partial J, \dots]).$$

In the formal bar model, $\mathcal{O}(\mathfrak{S}_b)$ is quasi-isomorphic to $\overline{B}(\mathcal{H}_k) = T^c(s^{-1}\mathbb{C} \cdot J)$.

- (ii) The (-1) -shifted symplectic structure on $\mathfrak{S}_b$ is:

$$\omega_{-1} = k \cdot d(s^{-1}J) \wedge d(s^{-1}J),$$

where $s^{-1}J$ is the desuspended generator of the bar complex. This is the canonical Liouville form on the (-1) -shifted cotangent $T^*[-1]\mathcal{L}_b$ restricted to $\mathfrak{S}_b$ via the Lagrangian self-intersection PTVV theorem.

- (iii) The convolution product on $H_*^{BM}(\mathfrak{S}_b)$ is: the Borel–Moore homology of $\mathfrak{S}_b$ with the convolution product is quasi-isomorphic, as a dg algebra, to $\mathcal{H}_k$ itself. That is:

$$H_*^{BM}(\mathfrak{S}_b) \simeq \mathcal{H}_k \simeq \mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{H}_k).$$

Proof. (i) The boundary algebra is $B = \mathcal{O}(\mathcal{L}_b) = \mathbb{C}[J, \partial J, \dots]$, a polynomial algebra. The ambient $\mathcal{O}(\mathcal{M}_{\text{vac}}) = \mathcal{O}(T^*[-2](\text{Maps}(D^2, V)))$ is the algebra of functions on the shifted cotangent. Writing J for the base coordinate and J^+ for the fiber coordinate (the antifield, of cohomological degree -2), we have $\mathcal{O}(\mathcal{M}_{\text{vac}}) = \mathbb{C}[J, \partial J, \dots, J^+, \partial J^+, \dots]$ with $|J^+| = -2$.

The inclusion $\mathcal{L}_b \hookrightarrow \mathcal{M}_{\text{vac}}$ is the zero section, so $\mathcal{O}(\mathcal{L}_b) = \mathcal{O}(\mathcal{M}_{\text{vac}})/(J^+, \partial J^+, \dots)$. The derived tensor product

$$B \otimes_{\mathcal{O}(\mathcal{M}_{\text{vac}})}^{\mathbb{L}} B \simeq B \otimes_{\mathcal{O}(\mathcal{M}_{\text{vac}})}^{\mathbb{L}} B$$

computes the derived self-intersection. Since B is cut out by the ideal $(J^+, \partial J^+, \dots)$ which is generated by a regular sequence (the antifields form a free module over $\mathcal{O}(\mathcal{M}_{\text{vac}})$), the Koszul resolution gives:

$$B \otimes_{\mathcal{O}(\mathcal{M}_{\text{vac}})}^{\mathbb{L}} \mathbb{C} \simeq \text{Sym}_B^c(\mathbb{L}_{\mathcal{L}_b/\mathcal{M}_{\text{vac}}}[\mathbb{1}]) \simeq \text{Sym}_B^c(\mathbb{T}_{\mathcal{L}_b}),$$

where the second step uses the Lagrangian identification $\mathbb{L}_{\mathcal{L}_b/\mathcal{M}_{\text{vac}}}[\mathbb{1}] \simeq \mathbb{T}_{\mathcal{L}_b}$.

For the full self-intersection $B \otimes_R^{\mathbb{L}} B$ (where $R = \mathcal{O}(\mathcal{M}_{\text{vac}})$), the two-sided bar resolution gives the bar complex $T^c(s^{-1}\bar{B})$ with bar differential.

Heisenberg simplification. Since $\mathcal{H}_k$ has only a single generator J and $m_k = 0$ for $k \geq 3$, the bar complex $\bar{B}(\mathcal{H}_k) = T^c(s^{-1}\mathbb{C} \cdot J)$ is the cofree coalgebra on a *one-dimensional* space. As a chain complex, it is:

$$\bar{B}(\mathcal{H}_k) : \quad \dots \rightarrow 0 \rightarrow \mathbb{C} \cdot (s^{-1}J)^{\otimes 2} \xrightarrow{d_{\bar{B}}} \mathbb{C} \cdot s^{-1}J \rightarrow 0 \rightarrow \dots$$

with $d_{\bar{B}}[(s^{-1}J)^{\otimes 2}] = k$. For $k \neq 0$, this is acyclic in positive degrees: $H^1(\bar{B}) = 0$, $H^2(\bar{B}) = \mathbb{C} \cdot c_k$ (the central extension class). The derived self-intersection is therefore homotopically 1-dimensional with a single nontrivial homology class.

(ii) The PTVV theorem gives a (-1) -shifted symplectic structure on the self-intersection of two Lagrangians in a (-2) -shifted symplectic stack. For the Heisenberg, the computation reduces to linear algebra. The conormal fiber of $\mathcal{L}_b$ in $\mathcal{M}_{\text{vac}}$ at the basepoint $J = 0$ is:

$$N_{\mathcal{L}_b/\mathcal{M}_{\text{vac}}}^*|_0 = \mathbb{C} \cdot J^+ \simeq \mathbb{C} \cdot s^{-1}J \cong \mathbb{T}_{\mathcal{L}_b}[-1]|_0.$$

The (-1) -shifted symplectic form on $\mathfrak{S}_b$ pairs the conormal direction from the first copy of $\mathcal{L}_b$ with that from the second. In bar coordinates, the two copies of $s^{-1}J$ (one from each factor) are paired by:

$$\omega_{-1} = k \cdot \langle s^{-1}J, s^{-1}J \rangle = k \cdot (ds^{-1}J)^{\wedge 2},$$

the Liouville form on $T^*[-1]\mathcal{L}_b$, with coefficient k inherited from the ambient (-2) -shifted pairing. The degree of ω_{-1} is (-1) : each $ds^{-1}J$ has degree $|s^{-1}J| + 1 = (-1) + 1 = 0$, and the wedge product has degree $0 + 0 - 1 = -1$ (the shift is from the symplectic structure, not from the generators).

More precisely: at the level of cotangent complexes, the PTVV pairing on $\mathfrak{S}_b = \mathcal{L}_b \times_{\mathcal{M}}^h \mathcal{L}_b$ is the composition

$$\mathbb{T}_{\mathfrak{S}_b} \simeq \text{cone}(\mathbb{T}_{\mathcal{L}_b} \oplus \mathbb{T}_{\mathcal{L}_b} \rightarrow \mathbb{T}_{\mathcal{M}}|_{\mathcal{L}_b})[-1] \xrightarrow{\omega_{-2}} \mathbb{L}_{\mathfrak{S}_b}[-1],$$

where the map uses the (-2) -shifted symplectic form ω_{-2} on $\mathcal{M}$. For Heisenberg, where $\mathcal{M} = T^*[-2](V_{\text{formal}})$ and $\mathcal{L}_b$ is the zero section, the cone reduces to $\mathbb{T}_{\mathcal{L}_b}[-1]$ (the conormal fiber), and the pairing is k times the canonical dual pairing. The resulting (-1) -shifted form is non-degenerate for $k \neq 0$.

(iii) The convolution algebra structure on $H_*^{\text{BM}}(\mathfrak{S}_b)$ is determined by the groupoid multiplication $\mathfrak{S}_b \times_{\mathcal{L}_b} \mathfrak{S}_b \rightarrow \mathfrak{S}_b$. In the bar model, this is the bar multiplication: the composition $\bar{B}(\mathcal{H}_k) \otimes_B \bar{B}(\mathcal{H}_k) \rightarrow \bar{B}(\mathcal{H}_k)$.

For the Heisenberg, the convolution reduces as follows. The bar complex $\bar{B}(\mathcal{H}_k) = T^c(s^{-1}\mathbb{C} \cdot J)$ is a cofree coalgebra on a one-dimensional cogenerating space. Its *linear dual* (the cobar construction) is

the free algebra on sJ :

$$\Omega(\overline{B}(\mathcal{H}_k)) = T(s \cdot s^{-1}J) = \mathbb{C}\langle J \rangle \simeq \mathcal{H}_k,$$

recovering the original algebra by bar-cobar inversion (Vol I, Theorem B; the Heisenberg is Koszul so $\Omega \circ \overline{B} = \text{id}$).

The Borel–Moore homology of the self-intersection, with the convolution product, computes the *endomorphism algebra* of the identity functor on $\mathcal{L}_b$ -modules, i.e., the Hochschild cochains of $B = O(\mathcal{L}_b)$:

$$H_*^{\text{BM}}(\mathfrak{S}_b) \simeq \text{HH}^\bullet(B) \simeq O(T^*[-1]\mathcal{L}_b) \simeq \mathbb{C}[J, \partial J, \dots, \xi, \partial \xi, \dots],$$

where $\xi = s^{-1}J^*$ is the fiber coordinate of degree (-1) on $T^*[-1]\mathcal{L}_b$. But for the Heisenberg, the derived center is $\mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{H}_k) = \mathcal{H}_k$ (the abelian case: Hochschild cohomology $\text{HH}^0(\mathcal{H}_k) = \mathcal{H}_k$ and higher $\text{HH}^n = 0$ for $n > 0$ in the relevant chiral Hochschild complex).

The key point is that for the Heisenberg, the Hochschild complex is concentrated:

$$\text{HH}_{\text{ch}}^n(\mathcal{H}_k, \mathcal{H}_k) = \begin{cases} \mathcal{H}_k & n = 0, \\ 0 & n \neq 0. \end{cases}$$

This is because $\mathcal{H}_k$ is commutative ($J_{(0)}J = 0$) and Koszul: the Hochschild–Kostant–Rosenberg spectral sequence degenerates, and since $\mathcal{H}_k$ has no nontrivial inner derivations (the bracket is trivial), all higher Hochschild cohomology vanishes.

Therefore, the convolution algebra is:

$$H_*^{\text{BM}}(\mathfrak{S}_b) \simeq \mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{H}_k) \simeq \mathcal{H}_k,$$

which is a commutative algebra (a polynomial algebra with the λ -bracket $\{J_\lambda J\} = k\lambda$). This is the bulk algebra: for the Heisenberg, the bulk equals the boundary, precisely because the algebra is abelian and the Lagrangian self-intersection is clean (transversal). $\square$

40.5 Summary: all three ingredients verified

THEOREM 40.6 (*Geometric Steinberg conjecture for Heisenberg*). For $A = \mathcal{H}_k$ with $k \neq 0$, all three ingredients of Conjecture ?? are verified:

Ingredient	Heisenberg verification
(a) (-2) -shifted symplectic $\mathcal{M}_{\text{vac}}$	$T^*[-2](\text{Maps}(D^2, V))$ with $\omega_{-2} = k \cdot \omega_{\text{can}}$ (Proposition 40.1)
(b) Lagrangian $\mathcal{L}_b$	Zero section $\text{Maps}(D^2, V) \hookrightarrow T^*[-2]$; conormal-tangent equivalence verified (Proposition 40.3)
(c) Convolution = bulk algebra	$H_*^{\text{BM}}(\mathfrak{S}_b) \simeq \mathcal{H}_k \simeq \mathcal{Z}_{\text{ch}}^{\text{der}}(\mathcal{H}_k)$ (Theorem 40.5)

Remark 40.7 (*Why Heisenberg is the right first check*). The Heisenberg verification is exact: no perturbative corrections, no higher A_∞ operations, no quantum group deformations. Every derived object reduces to a finite-dimensional chain complex, every fiber product is a linear algebra computation, and every convolution is a matrix multiplication. Yet none of the three ingredients is trivial: the (-2) -shifted symplectic

structure requires the BV formalism, the Lagrangian condition requires the symplectic non-degeneracy $k \neq 0$, and the convolution computation requires the bar complex and HKR identification.

The simplicity of the Heisenberg case makes the architecture of the conjecture visible. The three objects $(\mathcal{M}_{\text{vac}}, \mathcal{L}_b, \mathfrak{S}_b)$ are:

$$T^*[-2](V_{\text{formal}}) \supset V_{\text{formal}} \leftarrow V_{\text{formal}} \times_{T^*[-2](V_{\text{formal}})}^h V_{\text{formal}}.$$

The self-intersection of the zero section in a shifted cotangent bundle is the archetypal clean Lagrangian intersection: the excess bundle vanishes, the bar complex is formal, and the Steinberg object reduces to the Koszul complex. This is the geometric content of Koszulness for the Heisenberg algebra.

Remark 40.8 (What changes for Virasoro). For the Virasoro algebra (shadow depth $r_{\text{max}} = 4$), the Lagrangian self-intersection is *not* clean: the fourth-order pole $c/(z-w)^4$ creates excess intersection dimension, forcing $m_3 \neq 0$. The excess conormal bundle E is nontrivial, and the bar complex carries genuine higher operations. The self-intersection $\mathfrak{S}_b$ is singular, and the convolution algebra $H_*^{\text{BM}}(\mathfrak{S}_b)$ is no longer a polynomial algebra but a nontrivial deformation. Verifying the geometric Steinberg conjecture for Virasoro would require understanding this excess intersection geometry -- a genuine challenge that the Heisenberg case avoids entirely.

Remark 40.9 (Consistency with the Koszul dodecahedron). The Heisenberg verification is consistent with all twelve faces of the Koszul dodecahedron. In particular:

- *Concentration:* the bar cohomology is concentrated ($H^1 = 0$), confirming clean intersection.
- *Formality:* $m_k = 0$ for $k \geq 3$, confirming transversal meeting.
- *Spectral collapse:* the PBW spectral sequence degenerates at E_1 .
- *Lagrangian transversality:* the zero section meets itself transversally in $T^*[-2]$.

All twelve readings agree: the Heisenberg is the cleanest possible Lagrangian intersection, and the geometric Steinberg object is the simplest possible correspondence.

4I Prime locality: testing the arithmetic shadow at $p = 2, 3, 5$

The prime-locality conjecture (Vol I, Conjecture prime-locality-transfer in `arithmetic_shadows.tex`, line 5383) asserts that the shadow coefficients decompose prime-by-prime: $S_r^{(p)} \propto p_{r-1}(\alpha_p, \beta_p)$. Proved for lattice VOAs; trivially satisfied for Virasoro at leading $1/c$. We test the conjecture at primes $p = 2, 3, 5$ for the three simplest Virasoro minimal models.

Setup

The Virasoro shadow generating function satisfies $H(t, c)^2 = t^4 Q(t)$ with

$$Q(t) = c^2 + 12ct + \alpha(c)t^2, \quad \alpha(c) = 36 + \frac{80}{5c + 22},$$

so $H(t) = t^2 \sqrt{Q(t)}$ and $r \text{ Sh}_r = [t^r] H(t)$. The low-arity values are

$$\text{Sh}_2 = \frac{c}{2}, \quad \text{Sh}_3 = 2, \quad \text{Sh}_4 = \frac{10}{c(5c+22)}, \quad \text{Sh}_5 = \frac{-48}{c^2(5c+22)}.$$

For general $r \geq 4$, the shadow coefficient is a rational function of c with poles *only* at $c = 0$ and $c = -22/5$ (pole purity), of the form

$$r \operatorname{Sh}_r = \frac{N_r(c)}{c^{r-3} (5c+22)^{\lfloor (r-2)/2 \rfloor}},$$

where $N_r(c)$ is a polynomial with integer coefficients (the *numerator polynomial*).

The critical decomposition is

$$Q(t) = (c + 6t)^2 + \frac{80 t^2}{5c + 22}.$$

The first term generates the “free” shadow obstruction tower (the $c \rightarrow \infty$ limit); the perturbation $\varepsilon(c) := 80/(5c + 22)$, with $80 = 2^4 \cdot 5$, governs all non-free corrections.

The three test models are:

Model	c	$5c + 22$	Key primes
$\mathcal{M}(2, 5)$ (Lee–Yang)	$-22/5$	0	5
$\mathcal{M}(3, 4)$ (Ising)	$1/2$	$49/2$	2, 7
$\mathcal{M}(3, 5)$	$-3/5$	19	3, 5, 19

$\mathcal{M}(2, 5)$: the 5-adic wall

At $c = -22/5$, we have $5c + 22 = 0$, so the spectral curve acquires a cusp and $\alpha(c) \rightarrow \infty$. The shadow obstruction tower *degenerates*:

$$\operatorname{Sh}_2 = -\frac{11}{5}, \quad \operatorname{Sh}_3 = 2, \quad \operatorname{Sh}_r = \infty \text{ for } r \geq 4.$$

The 5-adic valuation $v_5(\kappa) = v_5(-11/5) = -1$. The Lee–Yang model is a *5-adic wall* in the moduli of Virasoro central charges: prime locality cannot hold in the naive sense because the tower degenerates. The singularity $5c + 22 = 0$ is the unique 5-integral obstruction locus of the shadow generating function.

$\mathcal{M}(3, 4)$ and $\mathcal{M}(3, 5)$: computed data

Ising $\mathcal{M}(3, 4)$, $c = 1/2$:

$$\begin{array}{lll} \operatorname{Sh}_2 = \frac{1}{4}, & \operatorname{Sh}_3 = 2, & \operatorname{Sh}_4 = \frac{40}{49}, \\ \operatorname{Sh}_5 = -\frac{384}{49}, & \operatorname{Sh}_6 = \frac{551680}{7203}, & \operatorname{Sh}_7 = -\frac{12625920}{16807}. \end{array}$$

$\mathcal{M}(3, 5)$, $c = -3/5$:

$$\begin{array}{lll} \operatorname{Sh}_2 = -\frac{3}{10}, & \operatorname{Sh}_3 = 2, & \operatorname{Sh}_4 = -\frac{50}{57}, \\ \operatorname{Sh}_5 = -\frac{400}{57}, & \operatorname{Sh}_6 = -\frac{1660000}{29241}, & \operatorname{Sh}_7 = -\frac{10400000}{22743}. \end{array}$$

The p -adic valuation tables

The universal $1/r$ normalization in $\operatorname{Sh}_r = [t^r] H(t)/r$ introduces spurious prime factors (e.g. the $1/7$ at $r = 7$). We report valuations of $r \operatorname{Sh}_r = [t^r] H(t)$, which removes this arithmetic noise.

Ising $\mathcal{M}(3, 4)$: $v_p(r \text{ Sh}_r)$ for $r = 2, \dots, 12$:

r	2	3	4	5	6	7	8	9	10	11	12
v_2	-1	1	5	7	9	11	13	15	17	19	21
v_3	0	1	0	1	0	2	0	1	0	1	0
v_5	0	0	1	1	1	1	1	1	1	1	1
v_7	0	0	-2	-2	-4	-4	-6	-6	-8	-7	-9

The $v_5 = 1$ column for $r \geq 4$ is a finite verified pattern (checked through $r = 25$ at seven central charges; see Proposition 4I.4 below). The v_2 column displays perfect linearity $v_2(r \text{ Sh}_r) = 2r - 3$ for $r \geq 4$.

$\mathcal{M}(3, 5)$: $v_p(r \text{ Sh}_r)$ for $r = 2, \dots, 12$:

r	2	3	4	5	6	7	8	9	10	11	12
v_2	0	1	3	4	6	8	7	8	9	10	11
v_3	1	1	-1	-1	-3	-2	-5	-5	-7	-7	-9
v_5	-1	0	2	3	4	5	6	7	8	9	10
v_{19}	0	0	-1	-1	-2	-2	-3	-3	-4	-4	-5

The v_{19} column is $-\lfloor (r-2)/2 \rfloor$ exactly through $r = 12$. The v_5 column satisfies $v_5 = r - 2$ for $r \geq 4$.

First result: linearity in $v_p(c)$

Let $c_k = 1/2^k$ for $k = 1, 2, 3, 4$ (all with $v_2(c_k) = -k$ but the same reduction modulo odd primes). The 2-adic valuations satisfy: $v_2(S_r)$ is a *perfect affine function* of $v_2(c)$ at each arity r , with slopes:

$$\text{slope}_r := \frac{\partial v_2(S_r)}{\partial v_2(c)} = \begin{cases} 1 & r = 2 \text{ (from } S_2 = c/2), \\ 0 & r = 3 \text{ (from } S_3 = 2, \text{ independent of } c), \\ -(r-2) & r \geq 4. \end{cases}$$

This is verified exactly for $r = 2, \dots, 12$ and $k = 1, 2, 3, 4$. The pattern for $r \geq 4$ reflects the recursion: $f_n = -(2c)^{-1} \sum f_j f_{n-j}$ introduces one factor of $1/c$ per step, and $S_r = f_{r-2}/r$ accumulates $(r-2)$ total factors of $1/c$ from the initial condition $f_0 = c$ (one factor of c) and the $(r-3)$ recursion steps (each contributing $1/c$), giving net exponent $1 - (r-3) - 1 = -(r-3)$; the additional -1 comes from the $1/c$ in $f_2 = 40/[c(5c+22)]$, yielding slope $-(r-2)$ overall.

Observation 4I.1 (Renormalised shadow coefficients). Define $\phi_r := S_r \cdot c^{r-2}$: the shadow coefficient with the leading power of $1/c$ extracted. Then $v_p(\phi_r)$ is *independent* of $v_p(c)$ for any prime p at which $v_p(5c+22)$ is also constant. This is verified by computation at $p = 2$ for $c \in \{1/2, 3/2, 5/2, 7/2\}$ (all giving $v_2(5c+22) = -1$): the vectors $(v_2(\phi_r))_{r=2}^{10}$ are identical across all four values. The same holds at $p = 3$ for $c \in \{2, 5, 11\}$ (all with $v_3(c) = v_3(5c+22) = 0$) and at $p = 5$ for $c \in \{-3/5, 2/5, 7/5, -8/5\}$ (all with $v_5(c) = -1, v_5(5c+22) = 0$).

The second result: failure of naive Euler product factorisation

The shadow coefficient $S_r(c)$ is a rational function of c alone. Its p -adic valuation depends on two quantities: $v_p(c)$ and $v_p(5c + 22)$. The dependence on $v_p(5c + 22)$ means that $v_p(S_r)$ is *not* determined by $v_p(c)$ alone: the “anomalous denominator” $5c + 22$ introduces cross-prime information. Explicitly:

- For $c = 2$ and $c = 4$, we have $v_2(c) = 1$ and $v_2(c) = 2$ respectively, while $v_2(5c + 22)$ equals 5 and 1. The 2-adic valuations $v_2(S_r)$ differ at $r = 4, 5, 6, \dots$
- At $p = 7$: central charges $c = 1, 2, 3, 5$ all have $v_7(c) = 0$ and $v_7(5c + 22) = 0$, but their $v_7(S_r)$ sequences differ starting at $r = 6$. The 7-adic valuation depends on finer arithmetic (the residue of c modulo higher powers of 7), not captured by the leading valuation data.

This rules out a naive Euler product factorisation $S_r = \prod_p S_r^{(p)}$ in which each local factor depends only on $v_p(c)$. The obstruction is structural: the shadow metric coefficient $\alpha(c)$ is a *rational function* of c , and v_p of a rational function depends on the full p -adic expansion of c , not just its leading digit.

The third result: weak p -adic locality at the shadow-coefficient level

Despite the failure of the naive factorisation, a weaker form of p -adic locality holds.

PROPOSITION 4I.2 (Weak p -adic locality). Fix a prime p and integers v, w . Let $\mathfrak{C}(p; v, w) := \{c \in \mathbb{Q}^\times : v_p(c) = v, v_p(5c + 22) = w\}$ be a “ p -adic class” of central charges. Then:

- At $p = 5$: for all $c_1, c_2 \in \mathfrak{C}(5; v, w)$, we have $v_5(S_r(c_1)) = v_5(S_r(c_2))$ for $r = 2, \dots, 10$. Verified for 7 central charges in the class $\mathfrak{C}(5; -1, 0)$ with distinct residues modulo 25.
- At $p = 2$: for all $c_1, c_2 \in \mathfrak{C}(2; -1, -1)$, we have $v_2(S_r(c_1)) = v_2(S_r(c_2))$ for $r = 2, \dots, 10$. Verified for 4 central charges $c \in \{1/2, 3/2, 5/2, 7/2\}$.
- At $p = 3$: for all $c_1, c_2 \in \mathfrak{C}(3; 0, 0)$, we have $v_3(S_r(c_1)) = v_3(S_r(c_2))$ for $r = 2, \dots, 10$. Verified for $c \in \{2, 5, 11\}$.
- At $p = 7$: weak locality *fails* for the class $\mathfrak{C}(7; 0, 0)$. Central charges $c = 1$ and $c = 2$ both have $v_7(c) = v_7(5c + 22) = 0$, but $v_7(S_6(1)) = 1 \neq v_7(S_6(2)) = 0$. The 7-adic structure depends on finer data than the valuation pair (v, w) .

The failure at $p = 7$ shows that the pair $(v_p(c), v_p(5c + 22))$ does not always suffice: the full p -adic expansion of c matters at primes that divide the numerator of $\alpha(c)$ through higher-order terms in the recursion.

The fourth result: anatomy of the anomalous prime

For the Ising model, the “anomalous prime” 7 enters through $5c + 22 = 49/2 = 7^2/2$. Its shadow obstruction tower factorisation is:

$$\begin{aligned} S_4 &= 2^3 \cdot 5 / 7^2, & v_7 &= -2, \\ S_6 &= 2^8 \cdot 5 \cdot 431 / 3 \cdot 7^4, & v_7 &= -4, \\ S_8 &= 2^{10} \cdot 5 \cdot 168221 / 7^6, & v_7 &= -6, \\ S_{10} &= 2^{16} \cdot 13 \cdot 4454767 / 7^8, & v_7 &= -8. \end{aligned}$$

The even-arity shadow coefficients have $v_7(S_{2k}) = -2(k-1)$: the power of 7 in the denominator grows at rate 2 per arity step. This is exactly $-v_7(\alpha) = 2$ per iteration of the square-root recursion (each step of $f_n = -(2c)^{-1} \Sigma$ propagates one power of $\alpha = 1924/49$, contributing $v_7(\alpha) = -2$). At odd arities, the pattern is $v_7(S_{2k+1}) \in \{-2(k-1), -2k+1\}$, reflecting the interplay between the cubic coupling $f_1 = 6$ (no 7-content) and the quartic coupling $f_2 = 40/(c(5c+22))$ (7-content from $5c+22 = 7^2/2$).

The anomalous prime 7 is the *Coxeter prime* for the Ising model: it arises from $5c+22$, which vanishes at the cusp $c = -22/5$ of the spectral curve. For a general minimal model $\mathcal{M}(p', p)$, the anomalous primes are those dividing $5c+22 = (27p'p - 30(p-p')^2)/(p'p)$.

The fifth result: the $\mathcal{M}(2, 5)$ singularity at $p = 5$

The Lee–Yang model $\mathcal{M}(2, 5)$ sits at $c = -22/5$, the cusp locus of the spectral curve. The curvature $\kappa = -11/5$ has $v_5(\kappa) = -1$. The shadow coefficient $S_4 = 10/(c(5c+22))$ diverges because $5c+22 = 0$. This is a *5-adic singularity*: the shadow obstruction tower does not converge in $\mathbb{Q}_5$.

From the spectral curve viewpoint: at $c = -22/5$, the discriminant $\Delta_t = -320c^2/(5c+22) \rightarrow \infty$, and the two branch points of $H(t) = t^2 \sqrt{Q_L(t)}$ collide. The spectral curve acquires a cusp. In 5-adic terms: the shadow coefficients S_r have poles at $c = -22/5$ of increasing order, and the 5-adic radius of convergence of the shadow obstruction tower (as a function of c) is bounded by $|c + 22/5|_5 > 0$.

This means $\mathcal{M}(2, 5)$ is a *5-adic boundary point*: the arithmetic of the shadow obstruction tower at the prime 5 is singular precisely because 5 divides the denominator of c . No local factor at 5 can be extracted by direct evaluation. The correct approach would require a 5-adic regularisation (analogous to the residue computation at a pole of the Epstein zeta function), which is beyond the scope of the present computation.

The sixth result: denominator-driven locality at D -primes

PROPOSITION 41.3 (*Finite denominator-driven locality verification*). Let $D(c) := 5c+22$ and let p be a prime with $v_p(D) > 0$ and $v_p(c) = 0$. In the verified ranges below,

$$v_p(r \text{ Sh}_r) = -\left\lfloor \frac{r-2}{2} \right\rfloor \cdot v_p(D),$$

with the numerator polynomial $N_r(c)$ contributing $v_p(N_r) = 0$. That is, the p -adic valuation is *purely determined by the pole structure* along $\{5c+22=0\}$ only up to the first numerator-prime exception.

Verified computationally: $p = 7$ for $\mathcal{M}(3, 4)$ through $r = 10$ (exact match; first failure at $r = 11$ where $7 \mid N_{11}(1/2)$); $p = 19$ for $\mathcal{M}(3, 5)$ through $r = 12$ (exact match, no failure observed).

Verification. For $\mathcal{M}(3, 4)$: $D = 49/2$, $v_7(D) = 2$, $v_7(c) = 0$. The predicted v_7 sequence for $r = 4, \dots, 10$ is $-2, -2, -4, -4, -6, -6, -8$, matching the table exactly. The denominator of $r \text{ Sh}_r$ contributes $D^{\lfloor (r-2)/2 \rfloor}$ to the 7-part, and $v_7(N_r(1/2)) = 0$ for $r = 4, \dots, 10$. At $r = 11$, $v_7(N_{11}(1/2)) = 1$: the numerator polynomial N_{11} acquires a factor of 7 when evaluated at $c = 1/2$.

For $\mathcal{M}(3, 5)$: $D = 19$, $v_{19}(D) = 1$, $v_{19}(c) = 0$. The predicted v_{19} sequence for $r = 4, \dots, 12$ is $-1, -1, -2, -2, -3, -3, -4, -4, -5$, matching the table exactly. $\square$

The D -prime valuations are *purely geometric*: they reflect the order of the pole of Sh_r along the divisor $\{5c+22=0\}$ in the c -moduli in the verified range. Beyond that range numerator primes can and do interfere.

The seventh result: universal $\mathfrak{s}$ -adic unit in the numerator

PROPOSITION 41.4 (*Finite $\mathfrak{s}$ -adic unit verification*). For the central charges and arities listed below,

$$v_{\mathfrak{s}}(N_r(c)) = 1.$$

Thus the numerator polynomial $N_r(c)$ carries exactly one factor of $\mathfrak{s}$ in the tested region. Verified at $c = 1/2, -3/5, 1/3, 7, -1, 25/3, 13$ through $r = 15$, and at $c = 7$ through $r = 25$. The universal statement is a conjectural pattern until a proof controls cancellations in the full numerator polynomial. The primitive numerator has baseline $\mathfrak{s}$ -content one in these computations, but special rational specialisations may acquire extra factors; for example $N_6(c) = 160(45c + 193)$ gains additional $\mathfrak{s}$ -adic valuation at $c = -188/45$.

Evidence. The spectral curve decomposes as $Q(t) = (c + 6t)^2 + \varepsilon t^2$ with $\varepsilon = 80/(5c + 22)$, where $80 = 2^4 \cdot 5$. The expansion of $\sqrt{(c + 6t)^2 + \varepsilon t^2}$ in powers of ε gives, at order k , a contribution proportional to ε^k , hence carrying $v_{\mathfrak{s}} \geq k$. The three relevant orders:

- (i) $k = 0$ (free tower): contributes $v_{\mathfrak{s}} = 0$ (the coefficients of $(c + 6t)$ are in $\mathbb{Z}[1/c]$).
- (ii) $k = 1$: the first-order correction is

$$\delta H = \frac{\varepsilon t^4}{2(c + 6t)} = \frac{40 t^4}{(5c + 22)(c + 6t)},$$

carrying $v_{\mathfrak{s}} = 1$ from the factor $40 = 2^3 \cdot 5$.

- (iii) $k \geq 2$: contributions carry $v_{\mathfrak{s}}(\varepsilon^k) = k \geq 2 > 1$, so they are $\mathfrak{s}$ -adically subdominant.

In the tested range no cancellation removes this first-order factor. A full theorem would require a no-cancellation argument for all higher terms and all rational central charges. $\square$

Remark 41.5 (Arithmetic origin of the factor of $\mathfrak{s}$). The factor of $\mathfrak{s}$ is traceable to the Virasoro OPE: the quartic contact term is $\text{Sh}_4 = 10/[c(5c + 22)]$, with $10 = 2 \cdot 5$. The generating function absorbs this into $\alpha - 36 = 80/(5c + 22)$, with $80 = 8 \cdot 10$. In the tested primitive numerators, every shadow coefficient at $r \geq 4$ inherits one baseline factor of $\mathfrak{s}$ from this quartic contact term. Extra factors can appear at special rational central charges, so the all- c statement remains conjectural.

The eighth result: a three-tier structure for p -adic locality

The data reveal a three-tier decomposition of the p -adic valuation of $r \text{ Sh}_r$:

- (i) *Primitive $\mathfrak{s}$ -tier* ($p = \mathfrak{s}$): the computations show $v_{\mathfrak{s}}(N_r) = 1$ for the listed central charges and arities, originating from the quartic contact coefficient $80/(5c+22)$. The unrestricted all- c statement is conjectural.
- (ii) *Geometric tier* ($p \mid 5c+22, p \nmid c$): v_p is exactly $-\lfloor (r-2)/2 \rfloor \cdot v_p(D)$, determined by the pole order along the Lee–Yang divisor. This holds below an arity threshold $r_p^*(c)$ (typically $r \leq 10-12$).
- (iii) *Algebraic tier* ($p \mid c$ or p divides the numerator polynomial N_r at specific c): v_p depends on both the pole structure *and* the evaluated numerator, carrying genuine arithmetic data of the specific algebra. The 2-adic structure is algebra-dependent: $v_2(N_6(1/2)) = 4$ while $v_2(N_6(-3/5)) = 6$ and $v_2(N_6(1/3)) = 9$.

New primes enter the numerator at specific arities (the *arithmetic thresholds*):

- $\mathcal{M}(3, 4)$: $13 \mid N_{10}(1/2)$ (first appearance); $7 \mid N_{11}(1/2)$ (breaking the geometric tier at $p = 7$); $17 \mid N_{11}(1/2)$.
- $\mathcal{M}(3, 5)$: $13 \mid N_7(-3/5)$; $37 \mid N_8(-3/5)$; $17 \mid N_{10}(-3/5)$.

Summary and diagnosis

- (1) The shadow obstruction tower $S_r(c)$ for Virasoro minimal models is a rational function of c , with denominators controlled by powers of c and $5c + 22$.
- (2) A naive Euler product $S_r = \prod_p S_r^{(p)}$ does *not* exist: the p -adic structure of S_r depends on finer data than the pair $(v_p(c), v_p(5c + 22))$, as shown by the $p = 7$ failure.
- (3) A weaker form of p -adic locality is verified only in the listed classes at $p = 2, 3, 5$. It is false in general, as the $p = 7$ counterexample above shows.
- (4) The “anomalous prime” of a minimal model $\mathcal{M}(p', p)$ is controlled by the primes dividing $5c + 22$. For the Ising model, this is 7; for Yang–Lee ($c = -3/5$), it is 19. These primes grow linearly in the denominator as r increases.
- (5) The Lee–Yang model $\mathcal{M}(2, 5)$ is a 5-adic singularity: the shadow obstruction tower diverges because $5c + 22 = 0$. No local factor at 5 exists without regularisation.
- (6) **(New)** The numerator polynomial $N_r(c)$ carries a baseline factor of 5 in the tested primitive cases. This finite verification points to, but does not prove, a universal arithmetic invariant originating from the Virasoro quartic contact coefficient $80/(5c+22)$ (Proposition 41.4).
- (7) **(New)** At D -primes (primes p dividing $5c + 22$ but not c), the p -adic valuation of $r \operatorname{Sh}_r$ is *exactly* $-\lfloor (r-2)/2 \rfloor \cdot v_p(D)$, determined purely by the pole structure along the Lee–Yang divisor. This geometric tier holds below an arity threshold $r_p^*(c)$ (Proposition 41.3).
- (8) **(New)** New primes enter the numerator polynomial at specific arities (arithmetic thresholds): 13 first appears at $r = 10$ for Ising, 7 first appears at $r = 11$ (breaking the geometric tier). These thresholds define a filtration on the shadow obstruction tower by arithmetic complexity.
- (9) The correct formulation of prime-locality for non-lattice algebras is at the *shadow-projection level* $\operatorname{Sh}_r(\Theta_{\mathcal{A}}; \tau)$, not at the coefficient level $S_r(c)$. The coefficient-level analysis shows that the “algebraic prime-locality” (Riccati determinacy) is an affine-linear structure in $v_p(c)$, but this does not imply the Euler product structure of the moment L -function $M_r(s)$, which requires additional input from the Hecke theory of quasi-modular forms.

Question 41.6 (p -adic regularisation of the Yang–Lee shadow). Is there a natural 5-adic regularisation of $S_r(\mathcal{M}(2, 5))$ obtained by taking the limit $c \rightarrow -22/5$ in $\mathbb{Q}_5$ with a prescribed normalisation? For a cusp singularity $H^2 \sim \alpha t^2$ (the leading term as $c \rightarrow -22/5$), the “renormalised” shadow coefficient is $\hat{S}_r := \lim_{c \rightarrow -22/5} (5c + 22)^{\lfloor r/2 \rfloor} S_r(c)$. If this limit exists and is nonzero in $\mathbb{Q}_5$, it would define a “local factor at 5” for the Lee–Yang theory.

Remark 41.7 (Connection to the arithmetic programme). The above computation confirms and refines the picture from the Vol I audit (Synthesis, §5 of `prime_locality/`). Specifically:

- The Euler product obstruction for Virasoro (Theorem `euler-koszul-standard`) operates at the *sewing-lift level* ($S_{\operatorname{Vir}}(u) = \zeta(u+1)(\zeta(u)-1)$, which has non-multiplicative Dirichlet coefficients). The present computation operates at the *shadow-coefficient level* ($S_r(c)$, which is a rational function of c). These are different objects.

- The weak p -adic locality of $S_r(c)$ is consistent with the Riccati determinacy theorem: the entire shadow obstruction tower is determined by (κ, α, S_4) via $H(t) = t^2 \sqrt{Q_L(t)}$, so the p -adic structure is controlled by the p -adic structure of these three invariants. The weak locality is precisely the statement that the square-root recursion preserves p -adic classes.
- Whether the moment L -function $M_r(s) = \int \text{Sh}_r \cdot E(s) d\mu$ has an Euler product remains the central open problem. This requires passing from the algebraic level (shadow coefficients, rational functions of c) to the analytic level (shadow amplitudes, quasi-modular forms on $\mathcal{M}_{1,1}$). The $E_2^*(\tau)$ obstruction is real and unresolved.

42 Complementarity constants K_N for the $\mathcal{W}_N$ family

This section computes the Koszul complementarity constants

$$K_N := \kappa(\mathcal{W}_{N,c}) + \kappa(\mathcal{W}_{N,c}^!)$$

for the principal $\mathcal{W}_N$ -algebra family ($N = 2, 3, 4, \dots$), verifying and extending the results of `w-algebras-stable.tex` (§??). The Virasoro case $K_2 = 13$ is the seed; the general formula reveals the harmonic number as the structural invariant governing the departure from anti-symmetry.

Input data

The principal $\mathcal{W}_N$ -algebra has generators W_s of conformal spin $s = 2, 3, \dots, N$ (with $W_2 = T$, the stress tensor). Three ingredients enter:

- (1) *Ghost central charge per spin.* The bc -ghost system for a spin- s current has conformal weights $(s, 1-s)$ and central charge

$$c_{\text{gh}}(s) = -2(6s^2 - 6s + 1).$$

This is the standard formula; the identity $2(6s^2 - 6s + 1) = 3(2s - 1)^2 - 1$ provides a convenient check.

- (2) *Total ghost charge and complementarity constant.*

$$\alpha_N = \sum_{s=2}^N |c_{\text{gh}}(s)| = \sum_{s=2}^N 2(6s^2 - 6s + 1) = 2(N-1)(2N^2 + 2N + 1).$$

The closed form follows from standard sum identities:

$$\begin{aligned} \sum_{s=2}^N (6s^2 - 6s + 1) &= N(N+1)(2N+1) - 6 - 3N(N+1) + 6 + (N-1) \\ &= N(N+1)(2N-2) + (N-1) \\ &= (N-1)[2N(N+1) + 1] = (N-1)(2N^2 + 2N + 1). \end{aligned}$$

- (3) *Per-generator curvature.* The leading scalar self-OPE of the spin- s generator is

$$W_{s(2s-1)} W_s = \frac{c}{s},$$

where c is the central charge of $\mathcal{W}_N$. This is the coefficient of the highest-order pole $(z - w)^{-2s}$ in the W_s - W_s OPE, normalised so that the cyclic pairing $\langle W_s, W_s \rangle = 1$. The formula c/s follows from the Bouwknegt–Schoutens normalisation of the principal $\mathcal{W}$ -algebra.

The curvature $\kappa(\mathcal{W}_{N,c})$

The modular characteristic is the sum of per-generator curvatures:

$$\kappa(\mathcal{W}_{N,c}) = \sum_{s=2}^N \frac{c}{s} = c \sum_{s=2}^N \frac{1}{s} = c (H_N - 1),$$

where $H_N = \sum_{j=1}^N 1/j$ is the N th harmonic number.

Verification:

- $N = 2$: $\kappa(\text{Vir}_c) = c \cdot (3/2 - 1) = c/2$. Matches Vol I.
- $N = 3$: $\kappa(\mathcal{W}_3) = c \cdot (1/2 + 1/3) = 5c/6$. Matches the engine (`holographic_ht_engine.py`).
- $N = 4$: $\kappa(\mathcal{W}_4) = c \cdot (1/2 + 1/3 + 1/4) = 13c/12$.
- $N = 5$: $\kappa(\mathcal{W}_5) = c \cdot (1/2 + 1/3 + 1/4 + 1/5) = 77c/60$.

The Koszul dual and complementarity sum

The Koszul dual of $\mathcal{W}_{N,c}$ is $\mathcal{W}_{N, \alpha_N - c}$. The Koszul involution is $c \mapsto \alpha_N - c$, with self-dual point $c_N^* = \alpha_N/2 = (N-1)(2N^2 + 2N + 1)$.

The curvature of the dual is

$$\kappa(\mathcal{W}_{N,c}^!) = \kappa(\mathcal{W}_{N, \alpha_N - c}) = (\alpha_N - c)(H_N - 1).$$

Therefore the complementarity sum is

$$K_N = \kappa(\mathcal{W}_{N,c}) + \kappa(\mathcal{W}_{N,c}^!) = c(H_N - 1) + (\alpha_N - c)(H_N - 1) = \alpha_N (H_N - 1).$$

This is *independent of c* (as it must be for a complementarity invariant) but *not zero* for $N \geq 2$.

Explicit values

N	α_N	$H_N - 1$	K_N	c_N^*	K_N/c_N^*
2	26	1/2	13	13	1
3	100	5/6	250/3	50	5/3
4	246	13/12	533/2	123	13/6
5	488	77/60	9394/15	244	77/30
6	850	29/20	2465/2	425	29/10
N	$2(N-1)(2N^2+2N+1)$	$H_N - 1$	$\alpha_N(H_N - 1)$	$(N-1)(2N^2+2N+1)$	$2(H_N - 1)$

The harmonic ratio

The ratio $K_N/c_N^* = 2(H_N - 1)$ reveals the structural content: the complementarity constant exceeds the self-dual central charge by the factor $2(H_N - 1)$, which grows logarithmically. For Virasoro ($N = 2$), this factor is exactly 1, so $K_2 = c_2^* = 13$ -- the coincidence that disguises the general pattern. For $N \geq 3$, $K_N > c_N^*$ strictly.

Observation 42.1 (Why $K_N = c_N^$ only for Virasoro).* The identity $K_N = c_N^*$ requires $2(H_N - 1) = 1$, i.e. $H_N = 3/2$. Since $H_2 = 3/2$ and H_N is strictly increasing, this holds only for $N = 2$. The Virasoro algebra is the *unique* member of the $\mathcal{W}_N$ family for which the complementarity sum equals the self-dual central charge.

The Kac–Moody contrast

For Kac–Moody algebras $V_k(\mathfrak{g})$, the Feigin–Frenkel involution $k \mapsto -k - 2h^\vee$ gives $\kappa + \kappa^\dagger = 0$. The Koszul involution is *anti-symmetric around the origin*. For $\mathcal{W}_N$, the involution $c \mapsto \alpha_N - c$ is anti-symmetric around $c_N^* = \alpha_N/2$, which is nonzero. The curvature $\kappa = c(H_N - 1)$ is linear in c , so the complementarity sum is $\alpha_N(H_N - 1) \neq 0$.

The root cause: Kac–Moody curvature is $\kappa = \dim(\mathfrak{g})(k + h^\vee)/(2h^\vee)$, which is linear in k with the Koszul involution $k \mapsto -k - 2h^\vee$ swapping $k + h^\vee \mapsto -(k + h^\vee)$, hence $\kappa \mapsto -\kappa$. For $\mathcal{W}_N$, the curvature $\kappa = c(H_N - 1)$ is linear in c but the involution $c \mapsto \alpha_N - c$ does not negate c ; it shifts it. The complementarity sum is the shift: $K_N = \alpha_N(H_N - 1)$.

Per-generator anatomy

The complementarity sum decomposes by spin:

$$K_N = \sum_{s=2}^N \left[\frac{c}{s} + \frac{\alpha_N - c}{s} \right] = \sum_{s=2}^N \frac{\alpha_N}{s} = \alpha_N \sum_{s=2}^N \frac{1}{s}.$$

The per-generator complementarity constant is $k_s = \alpha_N/s$. This depends on N (not just on s) because the central charge c parametrises all generators simultaneously: changing c shifts *every* OPE coefficient.

Contrast with the ghost charges: the per-generator ghost central charge $|c_{\text{gh}}(s)| = 2(6s^2 - 6s + 1)$ depends only on s , not on N . The ghost system for each spin is intrinsic. The ratio

$$\frac{k_s}{|c_{\text{gh}}(s)|} = \frac{\alpha_N}{s \cdot 2(6s^2 - 6s + 1)}$$

is *not* constant in s : higher-spin generators are “less efficient” at converting ghost central charge into complementarity.

Asymptotics

As $N \rightarrow \infty$:

$$\begin{aligned} \alpha_N &\sim 4N^3, \\ H_N - 1 &\sim \log N + \gamma - 1 \quad (\gamma = 0.5772 \dots \text{ Euler–Mascheroni}), \\ K_N &\sim 4N^3(\log N + \gamma - 1), \end{aligned}$$

$$c_N^* \sim 2N^3.$$

The complementarity constant grows as $N^3 \log N$, while the self-dual central charge grows as N^3 . The logarithmic factor is the harmonic series -- the signature of the sum over spins.

Remark 42.2 (Connection to the $\mathcal{W}_\infty$ limit). In the $\mathcal{W}_{1+\infty}$ limit, $H_N - 1 \rightarrow \infty$ and $\alpha_N \rightarrow \infty$, so $K_N \rightarrow \infty$: the complementarity constant diverges. This reflects the fact that $\mathcal{W}_{1+\infty}$ has infinitely many generators and the self-OPE contributions form a divergent harmonic series. Any finite truncation $\mathcal{W}_N$ has finite K_N , but the limit requires renormalisation of the complementarity sum -- a problem that does not arise for Kac–Moody algebras (where $K = 0$ identically).

Remark 42.3 (The three invariants of $\mathcal{W}_N$ Koszul duality). The Koszul duality of $\mathcal{W}_{N,c}$ is controlled by three data:

- (i) The complementarity constant $\alpha_N = 2(N-1)(2N^2 + 2N + 1)$, determining the Koszul involution $c \mapsto \alpha_N - c$.
- (ii) The curvature coefficient $H_N - 1 = \sum_{s=2}^N 1/s$, determining $\kappa = c(H_N - 1)$.
- (iii) The complementarity sum $K_N = \alpha_N(H_N - 1)$, the level-independent invariant.

The three are not independent: $K_N = \alpha_N(H_N - 1)$. But α_N (a polynomial in N) and $H_N - 1$ (a rational partial harmonic sum for each finite N , with logarithmic asymptotic character as $N \rightarrow \infty$) have entirely different analytic characters. The complementarity constant mixes polynomial and harmonic data.

43 $SU(2)$ Chern–Simons: low-arity A_∞ test

We record the low-arity A_∞ tests for the bar complex $\overline{B}(\widehat{\mathfrak{sl}}_{2,k})$, for $SU(2)$ Chern–Simons at level k on $\mathbb{R}_t \times \mathbb{C}_z$. The boundary chiral algebra is the affine Kac–Moody algebra $\widehat{\mathfrak{sl}}_2$ at level k , with OPE

$$J^a(z) J^b(w) \sim \frac{k \delta^{ab}}{(z-w)^2} + \frac{f^{ab}{}_c J^c(w)}{z-w}.$$

Poles of order at most 2: double from $k \delta^{ab}$, simple from $f^{ab}{}_c J^c$. No quartic pole.

43.1 Orthonormal basis and conventions

We work in the orthonormal basis $\{T^1, T^2, T^3\}$ of $\mathfrak{sl}_2$ with $[T^a, T^b] = \epsilon^{abc} T^c$, $g^{ab} = \delta^{ab}$, $\epsilon^{123} = +1$, and λ -bracket

$$\{T^a{}_\lambda T^b\} = \epsilon^{abc} T^c + \hat{k} \delta^{ab} \lambda, \tag{3}$$

where $\hat{k}$ is the level in this normalization. Key identity: $\epsilon^{acd} \epsilon^{bde} = \delta^{ab} \delta^{ce} - \delta^{ae} \delta^{cb}$.

43.2 The binary operation m_2

$$m_2(T^a, T^b; \lambda) = \epsilon^{abc} T^c + \hat{k} \delta^{ab} \lambda.$$

Linear in λ (not cubic as for Virasoro).

43.3 The nested-composition obstruction

PROPOSITION 43.1 (*Nested-composition obstruction for $\widehat{\mathfrak{sl}}_2$*).

$$\boxed{A_3(T^a, T^b, T^c; \lambda_1, \lambda_2) = 2\delta^{ac} T^b - \delta^{ab} T^c - \delta^{bc} T^a + \hat{k} \epsilon^{abc} \lambda_2.} \quad (4)$$

Proof. First composition. $m_2(T^a, T^b; \lambda_1) = \epsilon^{abp} T^p + \hat{k} \delta^{ab} \lambda_1$. Scalar killed by $\{\mathbf{1}_\lambda T^c\} = 0$.

$$\begin{aligned} \epsilon^{abp} m_2(T^p, T^c; \lambda_1 + \lambda_2) &= \epsilon^{abp} \epsilon^{pcq} T^q + \hat{k} \epsilon^{abc} (\lambda_1 + \lambda_2) \\ &= (\delta^{ac} \delta^{bq} - \delta^{aq} \delta^{bc}) T^q + \hat{k} \epsilon^{abc} (\lambda_1 + \lambda_2) \\ &= \delta^{ac} T^b - \delta^{bc} T^a + \hat{k} \epsilon^{abc} (\lambda_1 + \lambda_2). \end{aligned}$$

Second composition. $m_2(T^b, T^c; \lambda_2) = \epsilon^{bcp} T^p + \hat{k} \delta^{bc} \lambda_2$. Scalar killed.

$$\begin{aligned} \epsilon^{bcp} m_2(T^a, T^p; \lambda_1) &= \epsilon^{bcp} \epsilon^{apq} T^q + \hat{k} \epsilon^{abc} \lambda_1 \\ &= (\delta^{ab} \delta^{cq} - \delta^{ac} \delta^{bq}) T^q + \hat{k} \epsilon^{abc} \lambda_1 \\ &= \delta^{ab} T^c - \delta^{ac} T^b + \hat{k} \epsilon^{abc} \lambda_1. \end{aligned}$$

Difference: $A_3 = 2\delta^{ac} T^b - \delta^{ab} T^c - \delta^{bc} T^a + \hat{k} \epsilon^{abc} \lambda_2$. □

43.4 A_∞ -formality: $m_k^H = 0$ for $k \geq 3$ on cohomology

THEOREM 43.2 (*A_∞ -formality for $\widehat{\mathfrak{sl}}_2$*). The transferred A_∞ structure on the PVA cohomology $H^\bullet(\mathcal{A}_{CS}, Q) \simeq \widehat{\mathfrak{sl}}_{2,k}$ is formal: $m_k^H = 0$ for all $k \geq 3$. The nonzero associator (43.1) is compensated by the normally ordered product via the HPL transfer.

Proof. Two ingredients.

(1) **Lie conformal algebra structure.** The λ -bracket (43.1) satisfies the Lie conformal algebra Jacobi identity: $\{T^a_{\lambda_1} \{T^b_{\lambda_2} T^c\}\} - \{T^b_{\lambda_2} \{T^a_{\lambda_1} T^c\}\} = \{\{T^a_{\lambda_1} T^b\}_{\lambda_1 + \lambda_2} T^c\}$. For a Lie conformal algebra, the enveloping vertex algebra is well-defined (PBW theorem), and the A_∞ structure on the PVA is formal: the Lie conformal Jacobi identity encodes all homotopy-coherence data, so no higher operations are needed.

(2) **HPL transfer.** The vertex algebra $V_k(\widehat{\mathfrak{sl}}_2)$ is associative (Borcherds). The HPL formula for m_3^H is: $m_3^H(a, b, c) = p m_2^{\text{full}}(h m_2^{\text{full}}(i(a), i(b)), i(c)) + p m_2^{\text{full}}(i(a), h m_2^{\text{full}}(i(b), i(c)))$.

On weight-1 generators: $m_2^{\text{sing}}(T^a, T^b)$ produces weight-1 cocycles and scalars (both in $\ker h$), so $h \circ m_2^{\text{sing}} = 0$. The normally ordered product $:T^a T^b:$ is weight-2; $h(:T^a T^b:)$ is a weight-1 acyclic state. Feeding this into either m_2^{sing} or m_2^{reg} and projecting by p to weight-1 cohomology yields zero (the state is Q -exact).

Therefore $m_3^H = 0$. Induction extends to all m_k^H : every HPL tree for m_k^H contains at least one h -insertion mapping into the acyclic part, killed by p . □

Remark 43.3 (*Reconciling the nonzero associator with formality*). The displayed A_3 is a two-composition obstruction, not the full Lie conformal Jacobiator; the cyclic Jacobi sum cancels as it must. The obstruction $A_3 \neq 0$ and formality $m_3^H = 0$ are compatible. The Stasheff equation $A_3 = d m_3$ is solved at chain

level by a nonzero m_3 that is Q -exact. On cohomology, $p(\mathcal{A}_3) = 0$ because $\mathcal{A}_3$ is in the image of d : it is a coboundary, not a cocycle.

For Virasoro, the quartic-pole term $\frac{c}{12}\lambda_2^3(2\lambda_1 + \lambda_2)$ in the associator is a nontrivial cocycle (it cannot be written as d of anything), so $m_3^H \neq 0$. For KM, the associator is entirely built from Lie-bracket terms that ARE coboundaries.

43.5 Chain-level operations from Feynman diagrams

While $m_k^H = 0$ for $k \geq 3$ on cohomology, the chain-level A_∞ operations are nonzero:

PROPOSITION 43.4 (*Chain-level A_∞ structure*).

- (i) m_3 (triangle diagram): two cubic vertices, color $f^a_{de} f^{bc}$. Nonzero at chain level; Q -exact by Stokes on $FM_3(\mathbb{C})$.
- (ii) m_4 (square diagram): three cubic vertices, color $f^{ab}_g f^{gc}_h f^{hd}_e$. Its possible chain-level contribution requires an explicit $FM_4(\mathbb{C})$ integral and is not asserted here. Its cohomology class vanishes by the Lie conformal Jacobi identity and HPL transfer.
- (iii) **Higher arities**: no chain-level truncation is asserted in these notes. On cohomology, $m_k^H = 0$ for $k \geq 3$.

43.6 Koszul dual and complementarity

THEOREM 43.5 (*Koszul dual of $\widehat{\mathfrak{sl}}_{2,k}$*). Koszul dual level: $k' = -k - 2h^\vee = -k - 4$ (with $h^\vee = 2$). Curvature: $\kappa = 3(k+2)/4$. Complementarity: $\kappa + \kappa' = 0$ (not 13 as for Virasoro).

Proof. $\kappa' = 3(-k-4+2)/4 = -3(k+2)/4 = -\kappa$. The $2h^\vee$ shift: Verdier duality sends $k + h^\vee \mapsto -(k + h^\vee)$, so $k' = -k - 2h^\vee$. $\square$

Remark 43.6 (*Three duality operations, one affine output*).

Operation	Definition	Level
Koszul	$(H^\bullet(\overline{B}(\mathcal{A})))^\vee$	$-k - 4$
FF involution	$k \mapsto -k - 2h^\vee$	$-k - 4$
Negative level	$V_k \mapsto V_{-k}$	$-k$

Koszul and FF agree on the Koszul locus. $\widehat{\mathfrak{sl}}_{2,k}^1$ as a PVA is $\widehat{\mathfrak{sl}}_{2,-k-4}$ -PVA, but as a vertex algebra is $\text{Sym}^{\text{ch}}((\mathfrak{sl}_2)^*[-1])$, not $V_{-k-4}(\mathfrak{sl}_2)$.

43.7 Summary

PROPOSITION 43.7 (*Low-arity affine A_∞ summary*).

Datum	Value
m_2	$\epsilon^{abc} T^c + \hat{k} \delta^{ab} \lambda$
m_k^H (cohomology, $k \geq 3$)	$\circ$ (A_∞ -formal)
m_3 (chain level)	nonzero in the nested-composition model; Q -exact
m_4 and higher (chain level)	not asserted without explicit FM integrals
PVA associator	$2\delta^{ac} T^b - \delta^{ab} T^c - \delta^{bc} T^a + \hat{k} \epsilon^{abc} \lambda_2$
Shadow depth	3 (class L)
Koszul dual	$k' = -k - 4$
Curvature	$3(k+2)/4$
$\varkappa := \kappa + \kappa'$ (scalar)	$\circ$ (Trinity $K = c + c^\dagger = 2 \dim(\mathfrak{sl}_2) = 6$)
r -matrix	$r_{\text{OPE}} = k \Omega/z$; $r_{\text{KZ}} = \Omega/((k+2)z)$; $r_Y = \hbar \Omega/z$
Lines	$Y(\mathfrak{sl}_2)$ - mod

Remark 43.8 (Landscape comparison).

Family	$d_{\max}$	m_3^H	m_4^H	chain m_3	Class
Heisenberg	2	$\circ$	$\circ$	$\circ$	G , depth 2
KM $\widehat{\mathfrak{g}}_k$	2	$\circ$	$\circ$	$\neq \circ$	L , depth 3
$\beta\gamma$	1	$\neq \circ$	$\neq \circ$	$\neq \circ$	C , depth 4
Virasoro	4	$\neq \circ$	$\neq \circ$	$\neq \circ$	M , depth ∞

The key answer is cohomological: the A_∞ tower terminates on cohomology at arity 2 (strict formality). Chain-level operations are bookkeeping for the chosen resolution and require explicit configuration-space integrals before nonvanishing or truncation claims are made. The mechanism is the Lie conformal Jacobi identity: it makes the higher transferred operations Q -exact.

44 bc - $\beta\gamma$ Koszul duality: free-field test of the derived conjecture

The bc ghost system and the $\beta\gamma$ system are the two-generator free-field atoms. Their Koszul duality is the chiral incarnation of classical $\Lambda^* \leftrightarrow \text{Sym}^*$ duality. This section computes the Koszul dual of each system at general conformal weights, then of the combined $bc \otimes \beta\gamma$ system, and finally specialises to the string-theory point $(\lambda, \mu) = (2, 3/2)$. The computation tests Conjecture ?? of Volume I (the derived bc - $\beta\gamma$ Koszul duality conjecture).

44.1 Conventions and OPE data

We parametrise the bc system by a single conformal weight parameter $\lambda \in \mathbb{C}$:

- $b(z)$: fermionic, conformal weight $h_b = \lambda$,
- $c(z)$: fermionic, conformal weight $h_c = 1 - \lambda$.

The OPE is

$$b(z) c(w) = \frac{1}{z-w} + \text{reg.}, \quad c(z) b(w) = \frac{1}{z-w} + \text{reg.} \quad (5)$$

All other OPEs (including $b \cdot b$ and $c \cdot c$) are regular, by fermionic statistics.

We parametrise the $\beta\gamma$ system by a conformal weight parameter $\mu \in \mathbb{C}$:

- $\beta(z)$: bosonic, conformal weight $h_\beta = \mu$,

- $\gamma(z)$: bosonic, conformal weight $h_\gamma = 1 - \mu$.

The OPE is

$$\beta(z) \gamma(w) = \frac{1}{z-w} + \text{reg.}, \quad \gamma(z) \beta(w) = -\frac{1}{z-w} + \text{reg.} \quad (6)$$

Remark 44.1 (Central charges). The Virasoro central charges are:

$$c_{bc}(\lambda) = -2(6\lambda^2 - 6\lambda + 1) = 1 - 12\lambda(\lambda - 1), \quad (7)$$

$$c_{\beta\gamma}(\mu) = 2(6\mu^2 - 6\mu + 1). \quad (8)$$

Modular characteristics: $\kappa(bc) = c_{bc}/2 = -(6\lambda^2 - 6\lambda + 1)$ and $\kappa(\beta\gamma) = c_{\beta\gamma}/2 = 6\mu^2 - 6\mu + 1$.

Critical observation: at matching conformal weights $\mu = \lambda$, the central charges satisfy

$$c_{bc}(\lambda) + c_{\beta\gamma}(\lambda) = 0, \quad \kappa(bc_\lambda) + \kappa(\beta\gamma_\lambda) = 0. \quad (9)$$

This is exact complementarity (Theorem C) for the free-field Koszul pair: no shift by $\rho \cdot K$ as in the W-algebra case.

44.2 Koszul dual of the bc system

THEOREM 44.2 (*bc Koszul duality at general spins*). For any $\lambda \in \mathbb{C}$, the bc system with spins $(\lambda, 1-\lambda)$ is quadratically chiral Koszul, and its Koszul dual is the $\beta\gamma$ system at the *same* conformal weights:

$$(bc_\lambda)^\dagger \cong \beta\gamma_\lambda.$$

In particular, $h_{b^*} = h_\beta = \lambda$ and $h_{c^*} = h_\gamma = 1 - \lambda$: Koszul duality preserves the conformal weights and flips the statistics (fermionic $\leftrightarrow$ bosonic).

Proof. The bc system is quadratic: the generating space is $V = \mathbb{C}b \oplus \mathbb{C}c$ (fermionic, $\dim V = 2$) with the single quadratic relation

$$R_{bc} = \text{span}\{b \otimes c + c \otimes b\} \subset \text{Sym}^2(V).$$

This is a *symmetric* (Clifford-type) relation: the $+$ sign reflects the fermionic anticommutation $b(z_1)c(z_2) + c(z_2)b(z_1) \sim \frac{2}{z_1 - z_2}$ in the OPE, which the residue extraction $d \log(z_1 - z_2)$ converts to the bar differential identity $d_{\bar{B}}[s^{-1}b \mid s^{-1}c] + d_{\bar{B}}[s^{-1}c \mid s^{-1}b] = 0$ in bar degree 2.

Why $m_k = 0$ for $k \geq 3$. The OPE (44.1) has only a simple pole $1/(z-w)$. The bar differential component $d_k: \bar{B}^k \rightarrow \bar{B}^{k-1}$ at arity k involves the residue of the OPE integrated against a $(k-1)$ -form on $\text{FM}_k(\mathbb{C})$. For $k \geq 3$, the form degree exceeds the pole order: the collision of two points among k produces at most a simple pole, while the form $\eta_{i_1 i_2} \wedge \cdots \wedge \eta_{i_{k-1} i_k}$ contributes $k-1$ logarithmic factors. By dimensional analysis on the FM compactification, the residue integral vanishes for $k \geq 3$, giving $m_k = 0$. This is the same mechanism as for the Heisenberg algebra (Rosetta Stone, §??): quadratic OPE $\Rightarrow$ quadratic Koszulness.

Koszul dual. Under the residue pairing $\langle b, \beta \rangle = 1, \langle c, \gamma \rangle = 1$ (where $\beta = b^*$ and $\gamma = c^*$ denote the dual generators, which are bosonic by the parity flip), the orthogonal complement of R_{bc} is

$$R_{bc}^\perp = \text{span}\{\beta \otimes \gamma - \gamma \otimes \beta\} \subset \Lambda^2(V^*).$$

This is exactly the *antisymmetric* (Weyl-type) relation of the $\beta\gamma$ system. Since the OPE of bc is conformally covariant with weights $(\lambda, 1-\lambda)$, the dual generators inherit the same conformal weights: $h_\beta = h_b = \lambda, h_\gamma = h_c = 1 - \lambda$. Therefore

$$(bc_\lambda)^\dagger = \text{Free}^{\text{ch}}(V^*)/(R_{bc}^\perp) = \beta\gamma_\lambda. \quad \square$$

Remark 44.3 (Central charge under Koszul duality). Koszul duality does *not* negate the central charge as a scalar; it negates the *modular characteristic*. At matching spins:

$$\kappa((bc_\lambda)^\dagger) = \kappa(\beta\gamma_\lambda) = -\kappa(bc_\lambda),$$

so $\kappa + \kappa^\dagger = 0$ (exact complementarity, free-field family). Numerically:

$$c_{(bc_\lambda)^\dagger} = c_{\beta\gamma_\lambda} = -c_{bc_\lambda}.$$

The central charge *negates* under Koszul duality for this pair. This is a coincidence of the free-field family and should not be confused with the Kac–Moody level shift $k \mapsto -k - 2h^\vee$.

44.3 Koszul dual of the $\beta\gamma$ system

THEOREM 44.4 (*$\beta\gamma$ Koszul duality at general spins*). For any $\mu \in \mathbb{C}$, the $\beta\gamma$ system with spins $(\mu, 1-\mu)$ is quadratically chiral Koszul, and

$$(\beta\gamma_\mu)^\dagger \cong bc_\mu.$$

Proof. The argument is dual to Theorem 44.2. Generators: $V = \mathbb{C}\beta \oplus \mathbb{C}\gamma$ (bosonic, $\dim V = 2$). Relation: $R_{\beta\gamma} = \text{span}\{\beta \otimes \gamma - \gamma \otimes \beta\} \subset \Lambda^2(V)$ (antisymmetric, Weyl type). The orthogonal complement under the residue pairing is $R_{\beta\gamma}^\perp = \text{span}\{b \otimes c + c \otimes b\} \subset \text{Sym}^2(V^*)$, which is the Clifford relation of the bc system. The vanishing $m_k = 0$ for $k \geq 3$ follows from the same simple-pole argument. $\square$

Observation 44.5 (Involutivity). The Koszul duality is an involution on the free-field pair:

$$((bc_\lambda)^\dagger)^\dagger = (\beta\gamma_\lambda)^\dagger = bc_\lambda, \quad ((\beta\gamma_\mu)^\dagger)^\dagger = (bc_\mu)^\dagger = \beta\gamma_\mu.$$

This reflects the general fact that Koszul duality is an involution on the quadratic Koszul locus (Vol I, Theorem B).

44.4 Koszul dual of the combined $bc \otimes \beta\gamma$ system

We now address the tensor product. The combined system has generators $\{b, c, \beta, \gamma\}$ with the bc OPE (44.1) and the $\beta\gamma$ OPE (44.1), and *no cross-OPEs*:

$$b(z)\beta(w) \sim 0, \quad b(z)\gamma(w) \sim 0, \quad c(z)\beta(w) \sim 0, \quad c(z)\gamma(w) \sim 0. \quad (10)$$

THEOREM 44.6 (*Koszul duality distributes over the chiral tensor product*). Let $\lambda, \mu \in \mathbb{C}$ be arbitrary. Then the chiral tensor product $bc_\lambda \otimes^{\text{ch}} \beta\gamma_\mu$ is quadratically chiral Koszul, and

$$(bc_\lambda \otimes^{\text{ch}} \beta\gamma_\mu)^\dagger \cong \beta\gamma_\lambda \otimes^{\text{ch}} bc_\mu. \quad (11)$$

In particular, Koszul duality acts component-wise on the tensor factors, exchanging statistics in each sector while preserving conformal weights.

Proof. Both bc_λ and $\beta\gamma_\mu$ are quadratic chiral Koszul (Theorems 44.2 and 44.4). The vanishing of cross-OPEs (44.4) means the combined system is a genuine chiral tensor product in the sense of Vol I, Proposition ??: the generators decompose as $V = V_{bc} \oplus V_{\beta\gamma}$ and the relation space decomposes as $R = R_{bc} \oplus R_{\beta\gamma}$ (no mixed relations).

By the tensor product formula for quadratic chiral Koszul pairs (loc. cit.):

$$\begin{aligned} (bc_\lambda \otimes^{\text{ch}} \beta\gamma_\mu)^! &= \text{Free}^{\text{ch}}(V_{bc}^* \oplus V_{\beta\gamma}^*) / (R_{bc}^\perp \oplus R_{\beta\gamma}^\perp) \\ &= (bc_\lambda)^! \otimes^{\text{ch}} (\beta\gamma_\mu)^! \\ &= \beta\gamma_\lambda \otimes^{\text{ch}} bc_\mu. \end{aligned}$$

The central charge of the dual is

$$c_{(bc_\lambda \otimes \beta\gamma_\mu)^!} = c_{\beta\gamma_\lambda} + c_{bc_\mu} = -c_{bc_\lambda} - c_{\beta\gamma_\mu} = -c_{bc_\lambda \otimes \beta\gamma_\mu},$$

and complementarity holds: $\kappa_{\text{total}} + \kappa_{\text{total}}^! = 0$. □

Remark 44.7 (When $\lambda = \mu$: self-Koszul-dual tensor product). When the bc and $\beta\gamma$ systems have the *same* conformal weight parameter $\lambda = \mu$, the dual $\beta\gamma_\lambda \otimes bc_\lambda$ is the *same* algebra as $bc_\lambda \otimes \beta\gamma_\lambda$ (up to reordering of tensor factors). Thus the combined system is *self-Koszul-dual* at matching spins:

$$(bc_\lambda \otimes^{\text{ch}} \beta\gamma_\lambda)^! \cong bc_\lambda \otimes^{\text{ch}} \beta\gamma_\lambda.$$

This self-duality has central charge $c_{\text{total}} = 0$, $\kappa_{\text{total}} = 0$, reflecting exact boson–fermion cancellation. The bar complex of the combined system is acyclic (the Koszul complex is self-dual and exact), which is the algebraic shadow of the statement that the combined free-field system has vanishing conformal anomaly.

44.5 The string-theory point: $\lambda = 2$, $\mu = 3/2$

At the string-theory BRST point, the bc ghosts have spins $(2, -1)$ (i.e., $\lambda = 2$) and the $\beta\gamma$ superghosts have spins $(3/2, -1/2)$ (i.e., $\mu = 3/2$).

PROPOSITION 44.8 (*String-theory central charges*).

$$\begin{aligned} c_{bc}(2) &= -2(6 \cdot 4 - 6 \cdot 2 + 1) = -2 \cdot 13 = -26, \\ c_{\beta\gamma}(3/2) &= 2(6 \cdot 9/4 - 6 \cdot 3/2 + 1) = 2(27/2 - 9 + 1) = 2 \cdot 11/2 = 11. \end{aligned}$$

Total: $c_{\text{total}} = -26 + 11 = -15$. Modular characteristics: $\kappa(bc) = -13$, $\kappa(\beta\gamma) = 11/2$, $\kappa_{\text{total}} = -15/2$.

THEOREM 44.9 (*Koszul dual of the string ghost–superghost system*). The Koszul dual of the combined bc – $\beta\gamma$ ghost system at the string-theory point $(\lambda, \mu) = (2, 3/2)$ is:

$$(bc_2 \otimes^{\text{ch}} \beta\gamma_{3/2})^! \cong \beta\gamma_2 \otimes^{\text{ch}} bc_{3/2}.$$

The Koszul dual is a bosonic $\beta\gamma$ system at spins $(2, -1)$ tensored with a fermionic bc system at spins $(3/2, -1/2)$. Its central charge is

$$\begin{aligned} c_{\text{dual}} &= c_{\beta\gamma}(2) + c_{bc}(3/2) = 2 \cdot 13 + (-2)(6 \cdot 9/4 - 6 \cdot 3/2 + 1) \\ &= 26 + (-2)(11/2) = 26 - 11 = 15. \end{aligned}$$

This confirms $c_{\text{dual}} = -c_{\text{total}} = 15$ and $\kappa_{\text{dual}} = 15/2 = -\kappa_{\text{total}}$.

Proof. Immediate from Theorem 44.6 at $(\lambda, \mu) = (2, 3/2)$. The central charge computation is a direct substitution into (44.1) and (44.1). $\square$

Remark 44.10 (Physical interpretation).

- (i) *The Koszul dual is NOT the original system.* Since $\lambda \neq \mu$, the Koszul dual $\beta\gamma_2 \otimes bc_{3/2}$ is a *different* algebra from $bc_2 \otimes \beta\gamma_{3/2}$: the statistics assignment is swapped at *different* conformal weights. Concretely, the original system has a weight-2 fermion b and a weight-3/2 boson β ; the dual has a weight-2 boson β^* and a weight-3/2 fermion b^* .
- (ii) *The central charge flips sign but is nonzero.* The asymmetry $\lambda \neq \mu$ means $c_{\text{total}} = -15 \neq 0$, so the combined system is *not* self-Koszul-dual. The anomaly $c = -15$ is precisely the contribution that must be cancelled by $c = 15$ worth of matter in the $N = 1$ superstring (the superconformal matter has $c_{\text{matter}} = 15$ in the critical dimension $d = 10$).
- (iii) *Dual-level verification.* The Koszul dual central charge is $c_{\text{dual}} = 15 = -c_{\text{total}}$. This is *not* obtained by any level-negation prescription (there is no “level” for bc or $\beta\gamma$ in the Kac–Moody sense). Koszul duality acts by statistics exchange + sign flip of κ , not by any Feigin–Frenkel-type involution.
- (iv) *Complementarity and the superstring.* The full superstring BRST complex has $c_{\text{matter}} + c_{\text{ghosts}} = 15 + (-15) = 0$, and the Koszul dual of the ghost sector has $c = 15 = c_{\text{matter}}$. This is the free-field manifestation of complementarity (Theorem C): the Koszul dual of the ghost sector has the same central charge as the matter sector. The vanishing of the total anomaly is equivalent to the statement that the matter and ghost sectors form a Koszul-complementary pair.

44.6 Bar complex structure: explicit generators

PROPOSITION 44.11 (*Bar complex of bc_λ at genus 0*). The geometric bar complex $\overline{B}^{\text{ch}}(bc_\lambda)$ at genus 0 has:

- (i) $\overline{B}^0 = \mathbb{C}$ (vacuum).
- (ii) $\overline{B}^1 = \mathbb{C} \cdot [s^{-1}b] \oplus \mathbb{C} \cdot [s^{-1}c]$ ($\dim = 2$).
- (iii) The bar differential $d_{\overline{B}}: \overline{B}^2 \rightarrow \overline{B}^1$ is determined by

$$d_{\overline{B}}[s^{-1}b \mid s^{-1}c] = \text{Res}_{z_1=z_2} [b(z_1) c(z_2) \eta_{12}] = 1 \cdot [s^{-1}\mathbf{1}],$$

where $\mathbf{1}$ is the vacuum and the residue extracts the simple pole. The symmetric relation $d_{\overline{B}}[s^{-1}b \mid s^{-1}c] + d_{\overline{B}}[s^{-1}c \mid s^{-1}b] = 0$ encodes the Clifford relation.

- (iv) $\overline{B}^k = 0$ in bar cohomology for $k \geq 3$ (simple pole $\Rightarrow m_k = 0$ for $k \geq 3$).

The bar cohomology is $H^*(\overline{B}^{\text{ch}}(bc_\lambda)) \cong \text{Sym}^{\text{ch}}(\beta, \gamma)$ (the symmetric chiral algebra on two bosonic generators), confirming $(bc_\lambda)^! = \beta\gamma_\lambda$.

Proof. The only OPE with a pole is $b(z)c(w) \sim 1/(z-w)$ (simple pole of order 1). Since the bar kernel absorbs a pole, the collision residue is $r(z) = 1$ (constant), with pole order *one less* than the OPE: the $d \log(z-w)$ kernel absorbs the single power, leaving a finite residue.

At bar degree $k \geq 3$: a bar element $[s^{-1}a_1 | \cdots | s^{-1}a_k]$ lives on $\text{FM}_k(\mathbb{C})$ with $(k-1)$ logarithmic forms $\eta_{i_1 i_2} \wedge \cdots$. Each pairwise collision $z_i \rightarrow z_j$ produces at most a simple pole from the OPE, which is exactly absorbed by the $d \log$ propagator. The residue contributes to $d_{\bar{B}}$ at bar degree $k-1$, collapsing two of the k points. But for the *ternary* and higher operations, one needs a *simultaneous* multi-body collision on $\text{FM}_k(\mathbb{C})$, not just pairwise collisions. Since the OPE is strictly binary (no higher poles, no composite fields at coincident points), these multi-body contributions vanish.

Equivalently: the bc system is generated by $V = \mathbb{C}b \oplus \mathbb{C}c$ with a single quadratic relation. By the PBW criterion (Vol I, Theorem ??), the associated graded $\text{gr}_F(bc)$ is a Clifford algebra $\text{Cl}(V, q)$, which is classically Koszul (Priddy). The PBW spectral sequence degenerates at E_1 , confirming chiral Koszulness. $\square$

PROPOSITION 44.12 (*Bar complex of $\beta\gamma_\mu$ at genus 0*). The geometric bar complex $\bar{B}^{\text{ch}}(\beta\gamma_\mu)$ at genus 0 has:

- (i) $\bar{B}^1 = \mathbb{C} \cdot [s^{-1}\beta] \oplus \mathbb{C} \cdot [s^{-1}\gamma]$ ($\dim = 2$).
- (ii) The bar differential encodes the antisymmetric relation:

$$d_{\bar{B}}[s^{-1}\beta | s^{-1}\gamma] - d_{\bar{B}}[s^{-1}\gamma | s^{-1}\beta] = 0.$$

- (iii) $m_k = 0$ for $k \geq 3$ (same simple-pole argument).

The bar cohomology is $H^*(\bar{B}^{\text{ch}}(\beta\gamma_\mu)) \cong \Lambda^{\text{ch}}(b, c)$ (the exterior chiral algebra on two fermionic generators), confirming $(\beta\gamma_\mu)^! = bc_\mu$.

Proof. Identical to Proposition 44.11 with Clifford $\leftrightarrow$ Weyl exchange. The bosonic statistics of β, γ produce an antisymmetric relation $R_{\beta\gamma} \subset \Lambda^2(V)$, whose orthogonal complement is the symmetric relation $R_{bc} \subset \text{Sym}^2(V^*)$. $\square$

44.7 Genus-1 curvature

At genus $g = 1$, the bar complex acquires curvature $\kappa \cdot \omega_1$ (Vol I, Theorem D). For the bc system:

$$d_{\bar{B}}^2 = \kappa(bc_\lambda) \cdot \omega_1 = -(6\lambda^2 - 6\lambda + 1) \cdot \omega_1,$$

where $\omega_1 = c_1(\omega_{\bar{\mathcal{M}}_1})$ is the first Chern class of the Hodge bundle on $\bar{\mathcal{M}}_1$. For the Koszul dual:

$$d_{\bar{B}}^2 = \kappa(\beta\gamma_\lambda) \cdot \omega_1 = (6\lambda^2 - 6\lambda + 1) \cdot \omega_1 = -\kappa(bc_\lambda) \cdot \omega_1.$$

Curvature *negates* under Koszul duality, as required by complementarity.

At the string-theory point: $\kappa(bc_2) = -13$, so $d_{\bar{B}}^2 = -13\omega_1$. The Koszul dual has $\kappa(\beta\gamma_2) = +13$, giving $d_{\bar{B}}^2 = +13\omega_1$. The sum vanishes: $\kappa + \kappa^! = 0$. (Compare: for Virasoro at c , the self-duality point is $c = 13$ where $\kappa(\text{Vir}_c) = c/2 = 13/2$ and $\kappa(\text{Vir}_{26-c}) = (26-c)/2 = 13/2$, giving $\kappa + \kappa^! = 13 \neq 0$. The free-field pair has exact cancellation; the Virasoro pair does not.)

44.8 Relation to the derived conjecture

Conjecture ?? (Vol I) posits a *derived* Koszul duality between the free fermion $\mathcal{F} = \Lambda^{\text{ch}}(\psi^{(1)}, \psi^{(2)})$ (two fermionic generators) and the DG chiral algebra $(\beta\gamma \oplus bc, d_{\text{BRST}})$.

Observation 44.13 (What the computation confirms and what remains open).

- (i) *Confirmed:* The individual Koszul dualities $(\beta\gamma)^! \cong bc$ and $(bc)^! \cong \beta\gamma$ hold at all conformal weights (Theorems 44.2 and 44.4). These are the “single-pair dualities” referenced in the conjecture.
- (ii) *Confirmed:* Koszul duality distributes over the chiral tensor product for the decoupled $bc \otimes \beta\gamma$ system (Theorem 44.6). The distribution formula (44.6) is a consequence of the quadratic tensor product theorem (Vol I, Proposition ??).
- (iii) *Open:* The conjecture involves a *BRST differential* $d_{\text{BRST}}: bc \rightarrow \beta\gamma$ that *couple*s the two sectors. The decoupled tensor product (no cross-OPEs) is *not* the same as the BRST complex. The derived Koszul duality framework required to handle the coupled system does not yet exist: one needs a bar-cobar adjunction for DG chiral algebras (not just plain chiral algebras), extending the quadratic framework.
- (iv) *Open:* The conjecture identifies the derived Koszul dual of $\mathcal{F}(\psi^{(1)}, \psi^{(2)})$ (two free fermions) with the BRST complex $(\beta\gamma \oplus bc, d_{\text{BRST}})$. Our computation addresses the *reverse* direction: the Koszul dual of the combined (decoupled) $bc \otimes \beta\gamma$ system. The two directions are related but not identical, because the BRST differential introduces nontrivial higher A_∞ operations that break the tensor product structure.
- (v) *New evidence:* At matching spins $\lambda = \mu$, the combined system is self-Koszul-dual with $c = 0$ (Remark 44.7). This is consistent with the conjecture: when the BRST differential is trivial (no coupling), the derived pair degenerates to the tensor product of individual Koszul pairs, and self-duality is the algebraic expression of anomaly cancellation.

44.9 Summary table

System	Spins	c	κ	Koszul dual	$\kappa^!$
bc_λ	$(\lambda, 1-\lambda)$	$-2(6\lambda^2-6\lambda+1)$	$-(6\lambda^2-6\lambda+1)$	$\beta\gamma_\lambda$	$6\lambda^2-6\lambda+1$
$\beta\gamma_\mu$	$(\mu, 1-\mu)$	$2(6\mu^2-6\mu+1)$	$6\mu^2-6\mu+1$	bc_μ	$-(6\mu^2-6\mu+1)$
bc_2 (ghosts)	$(2, -1)$	-26	-13	$\beta\gamma_2$	13
$\beta\gamma_{3/2}$ (s.ghosts)	$(3/2, -1/2)$	11	$11/2$	$bc_{3/2}$	$-11/2$
$bc_2 \otimes \beta\gamma_{3/2}$	--	-15	$-15/2$	$\beta\gamma_2 \otimes bc_{3/2}$	$15/2$
$bc_\lambda \otimes \beta\gamma_\lambda$	--	0	0	self-dual	0

Remark 44.14 (Complementarity sum: universal vanishing for the free-field family). In every row, $\kappa + \kappa^! = 0$. This is the universal complementarity of the free-field family (class G and class C in the shadow classification). It fails for Virasoro ($\kappa + \kappa^! = 13$) and for general W-algebras ($\kappa + \kappa^! = \rho \cdot K \neq 0$ at shifted levels). The free-field case is the unique setting where Koszul complementarity is a strict sign flip.

44.10 Koszul dual $\neq$ spin flip

PROPOSITION 44.15 (*Koszul dual $\neq$ spin flip*). The Koszul dual $bc_\lambda^! = \beta\gamma_\lambda$ is *not* the bc system at dual spins $(1 - \lambda, \lambda)$. The central charges distinguish them:

$$\begin{aligned} c(bc_\lambda^!) &= c(\beta\gamma_\lambda) = 2(6\lambda^2 - 6\lambda + 1), \\ c(bc_{1-\lambda}) &= c(bc_\lambda) = -2(6\lambda^2 - 6\lambda + 1). \end{aligned}$$

These are equal only if $6\lambda^2 - 6\lambda + 1 = 0$, i.e., $\lambda = (3 \pm \sqrt{3})/6$. At all other values, the spin-flip and Koszul duality are distinct operations. Koszul duality changes statistics; spin-flip permutes generators within the same algebra.

Proof. The spin-flip $\lambda \mapsto 1 - \lambda$ sends $b \mapsto c'$, $c \mapsto b'$ with $c' = b$, $b' = c$: it is just a relabeling, and $c_{bc}(1 - \lambda) = c_{bc}(\lambda)$ (the formula is symmetric under $\lambda \mapsto 1 - \lambda$). Koszul duality sends $\wedge^{\text{ch}} \rightarrow \text{Sym}^{\text{ch}}$ and negates the central charge. These are completely different. $\square$

44.11 BRST anomaly cancellation under Koszul duality

THEOREM 44.16 (*Koszul duality preserves BRST anomaly cancellation for free-field string backgrounds*).

Let $\mathcal{A}_{\text{matter}} \otimes \mathcal{A}_{\text{ghost}}$ be a free-field BRST system with $c_{\text{matter}} + c_{\text{ghost}} = 0$. If all constituent algebras are free fields (tensor products of Heisenberg, bc , and $\beta\gamma$ systems), then

$$c_{\text{matter}}^! + c_{\text{ghost}}^! = 0.$$

The Koszul dual system is again BRST-anomaly-free.

Proof. By the tensor product formula (Theorem 44.6), it suffices to check each factor. For each factor, the complementarity constant $K = 0$:

- Heisenberg $\mathcal{H}_k$: $\kappa(\mathcal{H}_k^!) = -k$, so $K = k + (-k) = 0$.
- bc_λ : $K = c_{bc} + c_{\beta\gamma} = 0$ (equation (44.1)).
- $\beta\gamma_\mu$: $K = c_{\beta\gamma} + c_{bc} = 0$ (same identity).

Therefore the total complementarity constant of any tensor product of these systems is zero, and the BRST condition $c_{\text{total}} = 0$ implies $c_{\text{total}}^! = -c_{\text{total}} = 0$. $\square$

44.12 The curvature–Koszul dictionary

We collect the genus-1 curvatures for the full free-field family, including the Virasoro comparison.

Algebra	c	κ	Koszul dual	K
bc_ν	$-2(6\nu^2 - 6\nu + 1)$	$-(6\nu^2 - 6\nu + 1)$	$\beta\gamma_\nu$	0
$\beta\gamma_\nu$	$2(6\nu^2 - 6\nu + 1)$	$6\nu^2 - 6\nu + 1$	bc_ν	0
$\mathcal{H}_k$	1	k	$\text{Sym}^{\text{ch}}(V^*)$	0
Vir_c	c	$c/2$	Vir_{26-c}	13

The vanishing $K = 0$ for all free-field systems, and the nonvanishing $K = 13$ for Virasoro, confirm the general pattern: $K = 0$ when Koszul duality is the linear Ext/Sym exchange (free fields, affine KM, lattice VOAs), and $K \neq 0$ when Koszul duality involves the nonlinear DS reduction (Virasoro, $\mathcal{W}_N$).

45 Cardy asymptotics and BTZ entropy: conditional bar dictionary

The modular MC element Θ_{grav} of the Virasoro algebra records the genus-one and shadow data entering the standard Cardy/BTZ dictionary. The extraction of BTZ entropy requires the usual modular-invariance, vacuum-dominance, and Brown–Henneaux hypotheses.

The result is therefore a conditional algebraic dictionary from the single algebraic datum: the Virasoro λ -bracket $\{T_\lambda T\} = \partial T + 2T\lambda + (c/12)\lambda^3$.

45.1 The partition function from the genus tower

Write $q = e^{2\pi i\tau}$ for the modular parameter of the boundary torus $\partial(\text{solid torus})$. The genus-1 MC element $\Theta^{(1)}$ gives the one-loop partition function as the categorical trace:

$$Z_1(\tau) = \text{Tr}_{\text{Vir}_c} \left(q^{L_0 - c/24} \right) = \frac{q^{-c/24}}{\prod_{n=2}^{\infty} (1 - q^n)}.$$

The product starts at $n = 2$ because Vir_c has no weight-1 states (no affine currents: the graviton is spin-2).

The scalar-lane effective partition function, incorporating the bc ghost system with $c_{\text{ghost}} = -26$, is $Z_{\text{eff}}^{\text{scal}}(\tau) = \eta(\tau)^{-(c-26)/2}$.

Observation 45.1 (Two partition functions). The bar-complex framework distinguishes: (i) the *intrinsic* partition function $Z_1^{\text{intr}}(\tau) = \eta(\tau)^{-c/2}$ from the curvature $\kappa = c/2$; (ii) the *effective* partition function $Z_1^{\text{eff}}(\tau) = \eta(\tau)^{-(c-26)/2}$ from $\kappa_{\text{eff}} = (c - 26)/2$ after ghost subtraction. The Cardy formula uses the *full* Virasoro partition function, not the scalar-lane partition function.

45.2 Cardy asymptotics under modular hypotheses

Four steps: (1) highest-weight partition function; (2) modular S -transform; (3) saddle-point evaluation; (4) entropy extraction.

A BTZ black hole of mass M and angular momentum J corresponds to shifted cylinder energies

$$\Delta_{\pm} := L_0^{\pm} - \frac{c}{24} = \frac{M\ell \pm J}{2},$$

equivalently to highest weights $h_{\pm} = \Delta_{\pm} + c/24$. The partition function is $Z(\tau, \bar{\tau}) = \sum_{h, \bar{h}} d(h, \bar{h}) q^{h-c/24} \bar{q}^{\bar{h}-c/24}$. Modular invariance and vacuum dominance give, at high temperature, $Z \sim \exp(\pi c \text{Im}(-1/\tau)/12)$ (equivalently $\exp(\pi^2 c/(6\beta))$ in the real-temperature normalization). The saddle-point of $f(\tau) = \pi c/(12\tau) + 2\pi\tau\Delta_+$ is at $\tau_* = i\sqrt{c/(24\Delta_+)}$, giving $f(\tau_*) \approx 2\pi\sqrt{c\Delta_+}/6$, and similarly in the anti-holomorphic sector.

PROPOSITION 45.2 (*Cardy asymptotics under modular hypotheses*). The asymptotic entropy of the Virasoro bar complex at large shifted conformal energy is

$$S_{\text{Cardy}} = 2\pi\sqrt{\frac{c\Delta_+}{6}} + 2\pi\sqrt{\frac{c\Delta_-}{6}}.$$

Proof. Three bar-complex inputs: (i) curvature $\kappa = c/2$ determining vacuum energy $-c/24$; (ii) modular invariance from the genus-1 MC equation on $\mathcal{M}_{1,1}$; (iii) saddle-point at $\tau_* = i\sqrt{c/(24\Delta_+)}$. The algebraic

inputs are controlled by $\kappa = c/2$; the analytic modular and saddle hypotheses are additional assumptions. $\square$

45.3 BTZ black hole entropy

PROPOSITION 45.3 (*BTZ entropy under Brown–Henneaux/Cardy hypotheses*). The Bekenstein–Hawking entropy of the BTZ black hole is:

$$S_{\text{BTZ}} = \frac{2\pi r_+}{4G} = 2\pi\sqrt{\frac{c\Delta_+}{6}} + 2\pi\sqrt{\frac{c\Delta_-}{6}},$$

where $c = 3\ell/(2G)$ is the Brown–Henneaux central charge. Equivalently, $S_{\text{BTZ}} = 2\pi\sqrt{\kappa\Delta_+}/3 + 2\pi\sqrt{\kappa\Delta_-}/3$ with $\kappa = c/2$.

Proof. Substituting $c = 3\ell/(2G)$, $\Delta_+ = (M\ell + J)/2$, $\Delta_- = (M\ell - J)/2$ and using $M = (r_+^2 + r_-^2)/(8G\ell^2)$ and $J = r_+r_-/(4G\ell)$, equivalently $(r_+ \pm r_-)^2 = 8G\ell(M\ell \pm J)$, gives $S_{\text{BTZ}} = 2\pi r_+/(4G)$. $\square$

45.4 Verdier duality and the modular S -transform

PROPOSITION 45.4 (*Commutativity of $\mathbb{D}$ and S*). The Verdier involution $\mathbb{D}: c \mapsto 26 - c$ and the modular S -transform $\tau \mapsto -1/\tau$ commute: $S \circ \mathbb{D}(\Theta_{\text{Vir}_c}^{(1)}(\tau)) = \mathbb{D} \circ S(\Theta_{\text{Vir}_c}^{(1)}(\tau)) = \Theta_{\text{Vir}_{26-c}}^{(1)}(-1/\tau)$. They act on independent variables: algebraic data vs. modular parameter.

Observation 45.5 (*Paired Cardy formula on the real interval*). For $0 \leq c \leq 26$ and fixed shifted energy $\Delta \geq 0$, $S_{\text{Cardy}}(\text{Vir}_c; \Delta) + S_{\text{Cardy}}(\text{Vir}_{26-c}; \Delta) = 2\pi\sqrt{c\Delta/6} + 2\pi\sqrt{(26-c)\Delta/6}$. At the self-dual point $c = 13$ the two terms are equal; at $c = 26$ the dual contribution vanishes. The total counting capacity is bounded: $\sqrt{c} + \sqrt{26-c} \leq 2\sqrt{13}$, with equality at $c = 13$.

45.5 Summary

The bar complex supplies the Virasoro curvature and shadow data entering the Cardy expression. Identifying that expression with BTZ entropy is the Brown–Henneaux/Cardy step, not a theorem of the bar complex alone.

46 The critical scalar $C_{4,4;2;0,6}^{\text{res}}(4) = 2$: verification from the $\mathcal{W}_4$ OPE

The $\mathcal{W}_\infty$ stage-4 MC4 closure reduces, after the full Ward-normalized visible pairing reduction (Corollary ?? of Vol I), to a single scalar identity

$$C_{4,4;2;0,6}^{\text{res}}(4) = 2.$$

We verify this identity from first principles by three independent routes.

46.1 Route 1: the conformal Ward identity (universal for all s)

PROPOSITION 46.1 (*Universal self-coupling T -coefficient*). Fix $N \geq 2$. In any stage- N OPE calculus with Virasoro-primary generators $W^{(2)}, \dots, W^{(N)}$ satisfying the Zamolodchikov normalisation

$$\langle W^{(s)}(z) W^{(s)}(o) \rangle = \frac{c/s}{z^{2s}}, \quad c \neq 0,$$

the undifferentiated T -channel coefficient at the leading T -pole in the self-OPE satisfies

$$C_{s,s;2;0,2s-2}(N) = 2 \quad \text{for all } 2 \leq s \leq N.$$

In particular, $C_{4,4;2;0,6}(4) = 2$.

Proof. Write $N_s := c/s$ and consider the Virasoro Ward identity for the three-point function $\langle T(x) W^{(s)}(z) W^{(s)}(o) \rangle$:

$$\langle T(x) W^{(s)}(z) W^{(s)}(o) \rangle = \left[\frac{s}{(x-z)^2} + \frac{\partial_z}{x-z} + \frac{s}{x^2} + \frac{\partial_o}{x} \right] N_s z^{-2s}.$$

Here ∂_o acts on the position w in $(z-w)^{-2s}$ evaluated at $w = o$, giving $2s z^{-(2s+1)}$. Expanding for $|x| > |z|$ in the region $x^{-4} z^{-(2s-2)}$:

From $s \cdot z^{-2s}/(x-z)^2$. Use $1/(x-z)^2 = \sum_{n \geq 0} (n+1)(z/x)^n/x^2$. For $x^{-4} z^{-(2s-2)}$: need $n = 2$, coefficient $(n+1) = 3$. Contribution: $s \cdot 3 \cdot N_s$.

From $(-2s) \cdot z^{-(2s+1)}/(x-z)$. Use $1/(x-z) = \sum_{n \geq 0} (z/x)^n/x$. For $x^{-4} z^{-(2s-2)}$: need $n = 3$, coefficient 1. Contribution: $(-2s) \cdot 1 \cdot N_s$.

The remaining terms $s z^{-2s}/x^2$ and $2s z^{-(2s+1)}/x$ contribute only at $x^{-2} z^{-2s}$ and $x^{-1} z^{-(2s+1)}$ respectively, and do not reach $x^{-4} z^{-(2s-2)}$.

Summing:

$$[\text{Ward}]_{x^{-4} z^{-(2s-2)}} = N_s(3s - 2s) = s N_s = s \cdot \frac{c}{s} = c.$$

On the OPE side, the self-OPE $W^{(s)}(z) W^{(s)}(w)$ contains at pole order $2s - 2$ the undifferentiated T -primary channel $C_{s,s;2;0,2s-2} \cdot T(w)/(z-w)^{2s-2}$. Inserting into the three-point function and using $\langle T(x) T(o) \rangle = (c/2) x^{-4}$, the OPE produces at $x^{-4} z^{-(2s-2)}$:

$$[\text{OPE}]_{x^{-4} z^{-(2s-2)}} = C_{s,s;2;0,2s-2} \cdot \frac{c}{2}.$$

Equating and dividing by $c \neq 0$:

$$C_{s,s;2;0,2s-2} = \frac{c}{c/2} = 2. \quad \square$$

Remark 46.2 (Universality). The identity $C_{s,s;2;0,2s-2} = 2$ is independent of the algebra $\mathcal{W}_N$: it depends only on conformal symmetry and the normalisation convention. The Ward identity forces it for every Virasoro-primary generator of every $\mathcal{W}$ -algebra at every value of c , including the free-field realisation, the DS reduction, and the abstract bootstrap. In particular, it holds at $s = 2$ (the Virasoro TT OPE, giving $C_{2,2;2;0,2} = 2$ as the coefficient of T in $T(z)T(w) \sim (c/2)/(z-w)^4 + 2T(w)/(z-w)^2 + \partial T(w)/(z-w)$), at $s = 3$ (the $\mathcal{W}_3$ self-OPE, giving $C_{3,3;2;0,4} = 2$ already proved in Vol I), and at $s = 4$ (the critical identity).

46.2 Route 2: equivalence with the Zamolodchikov normalisation

PROPOSITION 46.3 (*Equivalence*). The identity $C_{4,4;2;0,6}(4) = 2$ is logically equivalent to the Zamolodchikov normalisation $\langle W^{(4)}(z) W^{(4)}(o) \rangle = (c/4) z^{-8}$, given the Virasoro Ward identity for the visible generators.

Proof. The proof of Proposition 46.1 shows:

$$C_{4,4;2;0,6} = 2 \iff {}_4 N_4 = c \iff N_4 = \frac{c}{4}.$$

The forward direction is the content of the proposition. The converse: if $C_{4,4;2;0,6} = 2$, then the Ward identity computation gives ${}_4 N_4 = 2 \cdot (c/2) = c$, hence $N_4 = c/4$. $\square$

Remark 46.4 (*Why the identity is non-trivial for MC₄*). The identity $C_{4,4;2;0,6} = 2$ is trivially true on the DS side: the DS reduction produces the $\mathcal{W}_4$ vertex algebra with standard normalisation, so $N_4 = c/4$ by construction. The non-trivial content is that the *residue side* $C_{4,4;2;0,6}^{\text{res}}(4)$, extracted from the bar differential of the factorisation target $\mathcal{W}_{\infty}^{\text{fact}}$, matches the DS value. This matching asserts that the stage-4 quotient of the factorisation target inherits the Zamolodchikov normalisation from the visible Virasoro package. The Ward identity proof (Proposition 46.1) shows that this inheritance is *automatic* once the visible generators are Virasoro-primary with the standard T -action -- no additional input from the DS reduction or the bootstrap is required.

This is the key observation that closes the identity: the hypotheses of the stage-4 MC₄ frontier package already include the Virasoro Ward identity for the visible generators, and this alone forces the T -channel coefficient at the leading T -pole to be 2.

46.3 Route 3: explicit DS computation

The principal Drinfeld–Sokolov reduction $\mathcal{W}_4 = \mathcal{W}(\mathfrak{sl}_4, f_{\text{prin}})$ provides an explicit, independent confirmation. In the DS construction with Zamolodchikov normalisation, the six stage-4 OPE coefficients are:

$$\begin{aligned} c_{334}^2 &= \frac{42 c^2 (5c + 22)}{(c + 24)(7c + 68)(3c + 46)}, \\ c_{444}^2 &= \frac{112 c^2 (2c - 1)(3c + 46)}{(c + 24)(7c + 68)(10c + 197)(5c + 3)}, \\ C_{3,4;3;0,4}^2 &= \frac{9}{16} c_{334}^2, & C_{3,4;4;0,3}^2 &= \frac{5}{7} c_{334}^2, \\ C_{4,4;2;0,6}^{\text{DS}} &= 2, & C_{3,4;2;0,5}^{\text{DS}} &= 0. \end{aligned}$$

The first four are the higher-spin targets (Hornfeck 1993, Blumenhagen–Eholzer–Flohr–Hornfeck–Hübel 1996); the last two are the theorematic Virasoro-target identities from the universal T -coupling (Proposition 46.1) and mixed-weight orthogonality.

No local compute oracle is invoked in this note; the displayed constants are carried by the Ward identity and the cited DS/OPE formulae.

46.4 Summary and consequences

THEOREM 46.5 (*The critical scalar identity*). The identity

$$C_{4,4;2;0,6}^{\text{res}}(4) = 2$$

holds as a theorem of conformal symmetry. More precisely:

- (i) The conformal Ward identity for $\langle T(x) W^{(4)}(z) W^{(4)}(o) \rangle$, under the Zamolodchikov normalisation, forces the coefficient $C_{4,4;2;0,6} = 2$ universally for any vertex algebra with a Virasoro-primary spin-4 generator.
- (ii) The identity is logically equivalent to the standard two-point normalisation $\langle W^{(4)}(z) W^{(4)}(o) \rangle = (c/4) z^{-8}$.
- (iii) The identity is a special case of the universal law $C_{s,s;2;0,2s-2} = 2$ valid for all conformal spins $s \geq 2$.
- (iv) The principal Drinfeld–Sokolov computation confirms it independently through the displayed OPE constants.

Remark 46.6 (Status within the MC₄ frontier). With this identity verified, the stage-4 Ward-inheritance conjecture (Conjecture ?? of Vol I) is resolved: the six-entry stage-4 identity packet contracts to the four higher-spin channels

$$(3, 3; 4; 0, 2), \quad (4, 4; 4; 0, 4), \quad (3, 4; 3; 0, 4), \quad (3, 4; 4; 0, 3).$$

Combined with the visible pairing reduction and Borchers transport, the remaining $\mathcal{W}_\infty$ stage-4 problem consists of the two primitive self-coupling square classes c_{334}^2 and c_{444}^2 . The $\mathcal{W}_4$ rigidity theorem (Zamolodchikov–Fateev–Lukyanov) then closes all stage-4 identities, resolving MC₄ at this stage. The true remaining frontier for $\mathcal{W}_\infty$ promotion is $N \geq 5$.

47 Genus-1 modular envelope: the first three operations

47.1 Setup and notation

The modular Swiss-cheese operad SC^{mod} has closed-color operations $\mathcal{E}^{\text{cl}}(g, n)$ for each genus $g \geq 0$ and arity $n \geq 0$ (subject to $2g - 2 + n > 0$). The genus-0 package is proved: the $\text{SC}^{\text{ch}, \text{top}}$ -algebra structure on a logarithmic chiral algebra $\mathcal{A}$ is the bar-cobar adjunction of Volume I Theorem A.

The *modular envelope* extends the genus-0 package to all genera via the relative Feynman transform $\text{FT}_{\text{Com}_{\text{mod}}/\text{SC}^{\text{ch}, \text{top}}}$. The genus-1 *seed* consists of the first three operations:

$$\begin{aligned} \mu_{1,0} : \mathbb{k} &\longrightarrow \mathbb{k}, & (\text{vacuum amplitude, arity } 0), \\ \mu_{1,1} : \mathcal{A} &\longrightarrow \mathbb{k}, & (\text{one-point function, arity } 1), \\ \mu_{1,2} : \mathcal{A}^{\otimes 2} &\longrightarrow \mathbb{k}, & (\text{two-point function, arity } 2). \end{aligned}$$

These are the genus-1 components $\Theta_{n=0}^{(1)}, \Theta_{n=1}^{(1)}, \Theta_{n=2}^{(1)}$ of the modular Maurer–Cartan element, computed from the genus-raising operator $D_1 = D_{\text{nsep}}$ acting on the genus-0 MC class $\Theta^{(0)}$.

47.2 The obstruction equation at genus 1

Fix $\mathcal{A}$ a logarithmic $\text{SC}^{\text{ch}, \text{top}}$ -algebra with genus-0 MC element $\Theta^{(0)} \in \text{MC}(\text{gr}_F^0 L_{\text{mod}})$. The universal genus-1 obstruction (Theorem ??) gives:

$$d_0^{\Theta^{(0)}} \Theta^{(1)} = -D_1(\Theta^{(0)}) = -\Delta_{\text{cyc}}(\Theta^{(0)}),$$

where Δ_{cyc} is the nonseparating self-sewing operator (the reduced cyclic odd Laplacian of Theorem ??).

The right-hand side is the *genus-1 forcing term*: the genus-raising operator applied to the tree-level data. The genus-1 MC element $\Theta^{(1)}$ is the unique (up to gauge) solution of this inhomogeneous equation, provided the obstruction class $\text{Ob}_1(\Theta^{(0)}) = [D_1 \Theta^{(0)}] \in H^2(\text{gr}_F^1 L, d_0^{\Theta^{(0)}})$ vanishes.

47.3 The computation for $\mathcal{A} = \text{Vir}_c$

We now specialise to the Virasoro algebra $\mathcal{A} = \text{Vir}_c$. The essential input data:

- Genus-0 MC element: $\Theta^{(0)} = \{m_2, m_3, m_4, \dots\}$, the full $\mathcal{A}_\infty$ structure from the OPE $T(z)T(w) \sim (c/2)/(z-w)^4 + 2T/(z-w)^2 + \partial T/(z-w)$.
- Modular characteristic: $\kappa(\text{Vir}_c) = c/2$.
- Cyclic inner product: $\langle L_{-n}, L_m \rangle = \frac{c}{12}(n^3 - n) \delta_{n,m}$ (the Shapovalov form).
- The triangular vanishing theorem: $\Delta_{\text{cyc}} P_\Pi = 0$ in $\mathcal{X}_{\text{loc}}^1 / \partial$ for the Virasoro PVA (Theorem ??).

47.3.1 $\mu_{1,0}$: the vacuum amplitude (torus partition function)

The arity-0 genus-1 MC element lives on the unique stable graph $\Gamma_{1,0}$ of genus 1 with no external legs: a single vertex with one self-loop. The nonseparating self-sewing operator contracts the binary vertex m_2 over the invariant form:

$$\mu_{1,0} = \Theta_{n=0}^{(1)} = \kappa(\text{Vir}_c) \cdot \omega_1 = \frac{c}{2} \omega_1 \in H^2(\overline{\mathcal{M}}_{1,1}),$$

where $\omega_1 = c_1(\lambda_{\text{Hodge}}) \in H^2(\overline{\mathcal{M}}_{1,1})$ is the Hodge class. The exponentiated partition function is the corresponding section of the Hodge determinant line; the curvature class itself is not an H^0 class.

The *genus-1 free energy* is the Hodge integral:

$$F_1(\text{Vir}_c) = \kappa \cdot \lambda_1^{\text{FP}} = \frac{c}{2} \cdot \frac{1}{24} = \frac{c}{48},$$

where $\lambda_1^{\text{FP}} = \int_{\overline{\mathcal{M}}_{1,1}} \lambda_1 = 1/24$ is Mumford's formula. The scalar partition function is

$$Z_1(\text{Vir}_c; \tau) = \eta(\tau)^{-\kappa} = \eta(\tau)^{-c/2} = q^{-c/48} \prod_{n=1}^{\infty} (1 - q^n)^{-c/2},$$

where $\eta(\tau) = q^{1/24} \prod_{n=1}^{\infty} (1 - q^n)$ is the Dedekind eta function and $q = e^{2\pi i \tau}$.

Remark 47.1 (Bar complex origin). The self-loop contraction sums over modes: $\Theta_{n=0}^{(1)} = \sum_{n \geq 1} \langle e^h | m_2 | e_h \rangle \cdot \omega_1 = \text{Tr}(L_0) \cdot \omega_1 = \kappa \cdot \omega_1$. Each factor $\eta(\tau)^{-1}$ in the partition function corresponds to one mode of the self-loop propagator on the torus. The total number of such modes is $\kappa = c/2$, the modular characteristic of Vol I Theorem D.

47.3.2 $\mu_{1,1}(T)$: the genus-1 one-point function

The arity-1 genus-1 element lives on the stable graph with one vertex, one self-loop, and one external leg (a tadpole²). The self-sewing contracts two of the three flags of the ternary vertex m_3 (from the Virasoro A_∞ structure) over the invariant form:

$$\mu_{1,1}(T) = \Theta_{n=1}^{(1)}(T) = -\frac{c}{24} E_2(\tau) \cdot T,$$

where $E_2(\tau) = 1 - 24 \sum_{n \geq 1} \sigma_1(n) q^n$ is the weight-2 quasi-modular Eisenstein series.

Derivation. The self-sewing of m_3 contracts a pair of flags using the Shapovalov form:

$$D_1(m_3)_{n=1}(T) = \sum_h \langle e^h | m_3(e_h, T) \rangle + \sum_h \langle e^h | m_3(T, e_h) \rangle.$$

The self-loop integral on the torus is

$$\oint_A \oint_B \frac{T(w)}{(z-w)^2} \frac{dz dw}{2\pi i} = \sum_{n \geq 1} n \cdot q^n \cdot T = \frac{E_2(\tau)}{24} T,$$

multiplied by the curvature factor $-\kappa = -c/2$ from the invariant-form contraction. Hence $\Theta_{n=1}^{(1)}(T) = -(c/2) \cdot E_2(\tau)/(12) \cdot T = -(c/24) E_2(\tau) \cdot T$.

Equivalently, this is the logarithmic derivative of the partition function:

$$\mu_{1,1}(T) = q \partial_q \log Z_1(\tau) \cdot T = -\frac{c}{24} E_2(\tau) \cdot T,$$

since $q \partial_q \log \eta(\tau) = -E_2(\tau)/24$ and $Z_1 = \eta^{-c/2}$. □

Remark 47.2 (Quasi-modularity as bar curvature). The quasi-modular anomaly of E_2 ($E_2(-1/\tau) = \tau^2 E_2(\tau) + 12\tau/(2\pi i)$) is the genus-1 incarnation of the curved bar differential $d_{\text{fib}}^2 = \kappa \cdot \omega_1 \neq 0$. The anomalous term is κ^{-1} times the nonseparating degeneration class. The non-holomorphic completion $\widehat{E}_2(\tau) = E_2(\tau) - 3/(\pi \text{Im } \tau)$ is a genuine modular form of weight 2; the correction $-3/(\pi \text{Im } \tau)$ is the contribution from the bulk (Koszul dual) sector.

47.3.3 $\mu_{1,2}(T, T)$: the genus-1 two-point function

The arity-2 genus-1 element lives on stable graphs with one vertex, one self-loop, and two external legs. The MC coefficient encodes the genus-1 connected two-point correlation function:

$$\mu_{1,2}(T, T; z_{12}) = \Theta_{n=2}^{(1)}(T, T; z_{12}) = \frac{c}{2} \wp(z_{12}; \tau) + 2 \langle T(z_1) T(z_2) \rangle_{g=1}^{\text{conn}}, \quad (12)$$

where $\wp(z; \tau)$ is the Weierstrass $\wp$ -function on the torus $E_\tau = \mathbb{C}/(\mathbb{Z} + \mathbb{Z}\tau)$ and $z_{12} = z_1 - z_2$.

More explicitly, the connected genus-1 two-point function is:

$$\langle T(z_1) T(z_2) \rangle_{g=1}^{\text{conn}} = \frac{c}{2} \left(\wp(z_{12}; \tau) + \frac{E_2(\tau)}{12} \right),$$

where $G(z; \tau) = -\log \vartheta_1(z|\tau) + \pi(\operatorname{Im} z)^2/\operatorname{Im} \tau + \text{const}$ is the scalar Green's function on the torus, and the Weierstrass $\wp$ -function with the $E_2/12$ correction arises as $\partial_z^2 G(z; \tau)$. The term $E_2(\tau)/12$ is the zero-mode subtraction ensuring $\int_0^1 G(z; \tau) dz = 0$.

Substituting:

$$\mu_{1,2}(T, T; z_{12}) = c \wp(z_{12}; \tau) + \frac{c}{12} E_2(\tau) + 2 G_2^T(z_1, z_2; \tau),$$

where G_2^T denotes descendant corrections at each conformal weight.

Derivation. Two channels contribute:

- (i) *Self-sewing of m_4* : the quartic vertex $m_4(T, T, e_h, e^h)$ is contracted over one pair of flags using the invariant form. The result is the propagator-exchange integral on the torus:

$$D_1(m_4)_{n=2} = \sum_h \langle e^h | m_4(T, T, e_h) \rangle = \frac{c}{2} \wp(z_{12}; \tau) + \dots$$

The Weierstrass $\wp$ -function emerges as the genus-1 chiral Green's function: it is the unique doubly-periodic meromorphic function with a double pole $1/z^2$ at $z = 0$, the elliptic replacement of the genus-0 propagator $1/(z_1 - z_2)^2$.

- (ii) *Composition $m_2 \circ m_2$ through the genus-1 propagator*: the product of two binary vertices joined by an internal edge propagating on the torus gives the descendant corrections:

$$\sum_{n \geq 0} \langle T(z_1) | q^{L_0 - c/24} | T(z_2) \rangle = E_2(\tau) \cdot (T \otimes T) + \dots$$

The total is (47.3.3). □

47.4 Swiss-cheese structure of $\mu_{1,n}$

We now describe the structural features of the genus-1 seed.

47.4.1 Factorisation through the relative Feynman transform

PROPOSITION 47.3 (*Factorisation of $\mu_{1,n}$; computed here*). The genus-1 operations $\mu_{1,n}$ factor through the relative Feynman transform $\text{FT}_{\text{Com}_{\text{mod}}/\text{SC}^{\text{ch}, \text{top}}}$ as follows. Each $\mu_{1,n}$ is the genus-1 component of the modular MC element $\Theta_{\mathcal{A}}$, which is the universal twisting morphism of the FT_{rel} -algebra structure on $B^{\text{mod}}(\mathcal{A})$:

$$B^{\text{mod}, (0)}(\mathcal{A}) \xrightarrow{D_1} B^{\text{mod}, (1)}(\mathcal{A}) \xrightarrow{\text{proj}_n} \mathcal{A}^{\otimes n}$$

where $D_1 = D_{\text{nsep}}$ is the genus-raising differential of the bicomplex (D_0, D_1) , and proj_n projects to the genus-1, arity- n corolla.

Concretely:

- (i) $\mu_{1,0}$ is the trace of D_1 on the genus-0 bar complex: it picks out the self-sewing of m_2 at the arity-0 corolla, producing the scalar curvature $\kappa \cdot \omega_1$.
- (ii) $\mu_{1,1}$ is the composition $\text{proj}_1 \circ D_1 \circ \Theta_{n=3}^{(0)}$: the genus-raising differential applied to the ternary vertex m_3 , projected to arity 1.

- (iii) $\mu_{1,2}$ is the sum of $\text{proj}_2 \circ D_1 \circ \Theta_{n=4}^{(o)}$ (self-sewing of m_4) and the separating contribution $m_2 \circ_{(1)} m_2$ through the genus-1 propagator.

47.4.2 The two colors at genus 1

At genus 1, the Swiss-cheese structure has:

- *Closed color* (modular): the self-sewing $\xi_{ij}: \mathcal{E}^{\text{cl}}(o, I) \rightarrow \mathcal{E}^{\text{cl}}(1, I \setminus \{i, j\})$ is the genus-raising clutching that converts two closed flags into a self-loop. This is $D_1 = D_{\text{nsep}}$. The closed-color data at genus 1 is the curvature $\kappa(\mathcal{A}) \cdot \omega_1$, a scalar.
- *Open color* (boundary): the boundary algebra $\mathcal{A}_b = \text{End}(b)$ inherits genus-1 corrections via the bulk-to-boundary map. The genus-1 boundary correction is $\Theta_{n=1}^{(1)}(T) = -(c/24) E_2(\tau) \cdot T$, which is the Casimir energy density on the torus.

The directionality is strict: $\mu_{1,n}$ with $n \geq 1$ encodes bulk observables *restricting* to boundary corrections (the E_2 and $\wp$ terms), but there is no map from the boundary back to the genus-1 bulk. This is Axiom 5 of the relative modular extension.

47.4.3 The curvature–braiding dichotomy at genus 1

The spectral braiding dichotomy governs the genus-1 operations:

- The curvature $\kappa \cdot \omega_1$ sources $\mu_{1,o}$ (the scalar partition function). It lives in the closed color and is controlled by the *highest-pole coefficient* of the λ -bracket.
- The $E_2(\tau)$ corrections in $\mu_{1,1}$ and the $\wp(z; \tau)$ kernel in $\mu_{1,2}$ are controlled by the *lowest-pole coefficient* $c_o = \{T \circ T\}$ of the λ -bracket. For the Virasoro algebra, $\{T \circ T\} = \partial T \neq o$ (the zeroth product is nonzero), so the genus-1 braiding is in the *entangled* (Yangian-type) regime: the curvature and braiding share a common geometric source in the quasi-periodicity of the Weierstrass ζ -function.

47.5 General structure: $\mu_{1,n}$ for arbitrary n

The pattern extends to all arities.

PROPOSITION 47.4 (*General genus-1 operation; computed here*). For a logarithmic $\text{SC}^{\text{ch}, \text{top}}$ -algebra $\mathcal{A}$ with genus-0 MC element $\Theta^{(o)}$, the genus-1 MC element at arity n is:

$$\Theta_n^{(1)} = \sum_{k \geq n+2} \text{proj}_n \circ D_1 \circ \Theta_k^{(o)} + \sum_{\substack{k_1+k_2=n+2 \\ k_1, k_2 \geq 2}} \Theta_{k_1}^{(o)} \circ_{(1)} \Theta_{k_2}^{(o)} \Big|_{\text{genus-1 propagator}},$$

where the first sum runs over self-sewings of genus-0 vertices of arity $k \geq n+2$ (contracting two of the k flags into a self-loop, leaving n external legs), and the second sum runs over separating compositions that propagate through a genus-1 Green's function.

For the Virasoro algebra:

- (a) $n = 0$: only the $k = 2$ self-sewing contributes $\Rightarrow \mu_{1,o} = \kappa \cdot \omega_1 = (c/2) \omega_1$.
- (b) $n = 1$: the $k = 3$ self-sewing dominates $\Rightarrow \mu_{1,1}(T) = -(c/24) E_2(\tau) \cdot T$.
- (c) $n = 2$: the $k = 4$ self-sewing plus the $m_2 \circ m_2$ propagation $\Rightarrow \mu_{1,2}$ involves $\wp(z; \tau)$ and $E_2(\tau)$.

- (d) $n = 3$: the $k = 5$ self-sewing plus lower compositions $\Rightarrow \mu_{1,3}$ involves $\wp'(z; \tau)$ (the derivative of the Weierstrass $\wp$ -function).
- (e) $n \geq 4$: the genus-1 n -point function involves $\wp^{(n-2)}(z; \tau)$ and descendant corrections at each level.

The general pattern: the genus-1 n -point function on the torus replaces the genus-0 rational propagator $1/(z_i - z_j)^k$ by its elliptic counterpart $\wp^{(k-2)}(z_i - z_j; \tau)$, plus quasi-modular corrections from zero-mode subtractions. The bar complex governs this replacement systematically: D_1 is the algebraic machine that produces the elliptic propagators from the genus-0 OPE data.

47.6 Summary

Operation	Bar complex origin	Virasoro value	Modular function
$\mu_{1,0}$	$\text{Tr}(D_1 \circ m_2)$	$(c/2) \omega_1$	$\eta(\tau)^{-c/2}$
$\mu_{1,1}(T)$	$\text{proj}_1 \circ D_1 \circ m_3$	$-(c/24) E_2(\tau) T$	Quasi-modular weight 2
$\mu_{1,2}(T, T)$	$D_1 \circ m_4 + m_2 \circ m_2$	$c \wp(z_{12}) + (c/12) E_2$	Weierstrass $\wp + E_2$

The three operations exhibit a uniform structure:

- (i) Each $\mu_{1,n}$ is produced by the genus-raising differential $D_1 = D_{\text{nsep}}$ of the relative Feynman transform acting on genus-0 data of arity $\geq n + 2$.
- (ii) Each factors through the modular bar coalgebra $B^{\text{mod}}(\mathcal{A})$ and its bicomplex (D_0, D_1) .
- (iii) The modular functions that appear ($\eta, E_2, \wp$) are the elliptic replacements of the rational genus-0 propagators, systematically generated by the self-sewing mechanism.
- (iv) The curved bar differential $d^2 = \kappa \cdot \omega_1$ is visible at every arity: it sources $\mu_{1,0}$ directly, it controls the quasi-modular anomaly of $\mu_{1,1}$, and it appears as the E_2 -correction in $\mu_{1,2}$.

This completes the genus-1 seed of the modular envelope. The genus-2 entry point involves three channels ($\Delta_{\text{cyc}}(K_{1,1})$, $\frac{1}{2}[K_{1,1}, K_{1,1}]$, and rigid-boundary residues) and is the subject of the next computation.

48 Purity–Koszulness: testing beyond the affine lineage

The semisimple purity criterion (Theorem thm:semisimple-purity in bar-cobar-review.tex) establishes

$$\text{collision purity} \iff \text{chiral Koszulness}$$

for chiral algebras whose effective OPE residues Ω_{ij}^{eff} are semisimple endomorphisms. The theorem is verified for the affine lineage: $V^k(\mathfrak{g})$, $\beta\gamma$, Landau–Ginzburg, and abelian Chern–Simons. This section tests the correspondence for three families outside the affine lineage: *lattice VOAs*, *orbifold VOAs*, and *coset VOAs* (Virasoro minimal models via GKO). We also investigate the sharpness of the one-loop criterion (Theorem thm:one-loop-koszul) and determine the Koszul locus of $\mathcal{W}_3$ via the DS obstruction theorem (Theorem thm:ds-koszul-obstruction).

48.1 Lattice VOAs: V_L for $L = A_2, D_4$

Let L be an even lattice of rank r . The lattice VOA V_L has generators: Heisenberg currents $J^a(z)$ ($a = 1, \dots, r$) and vertex operators $V_\alpha(z) = e^\alpha(z)$ for $\alpha \in L$. The OPE data is:

$$J^a(z)J^b(w) \sim \frac{\langle e_a, e_b \rangle}{(z-w)^2}, \quad (13)$$

$$J^a(z)V_\alpha(w) \sim \frac{\langle e_a, \alpha \rangle V_\alpha(w)}{z-w}, \quad (14)$$

$$V_\alpha(z)V_\beta(w) \sim \epsilon(\alpha, \beta) (z-w)^{\langle \alpha, \beta \rangle} V_{\alpha+\beta}(w) + \dots \quad (15)$$

48.1.0.1 Effective residue analysis. The double-pole term in (48.1) is *scalar* (it takes values in $\mathbb{C} \cdot \mathbf{1}$), so it contributes to the curvature $m_o = \kappa(V_L)$ and is projected away in the effective residue.

The simple-pole term in (48.1) has residue $\langle e_a, \alpha \rangle \cdot V_\alpha$, which acts *diagonally* on the vertex-operator sector: on the tensor product $V_L^{\otimes 2}$, the effective residue Ω_{12}^{eff} restricted to the $J^a \otimes V_\alpha$ sector is the scalar $\langle e_a, \alpha \rangle$. This is trivially semisimple (scalar on each sector).

The vertex-operator OPE (48.1) has pole of order $-\langle \alpha, \beta \rangle$ (negative for $\langle \alpha, \beta \rangle > 0$, meaning a zero rather than a pole). When $\langle \alpha, \beta \rangle < 0$ (as happens for roots in opposite Weyl chambers), the residue coefficient $\epsilon(\alpha, \beta) V_{\alpha+\beta}$ is proportional to a single vertex operator, hence acts by rank 1 on the tensor product. In particular, the effective residue on the $V_\alpha \otimes V_\beta$ sector (for α, β with $\langle \alpha, \beta \rangle < 0$) is a *scalar multiple* of the projection onto $V_{\alpha+\beta}$ -- semisimple because it is a rank-1 projector up to scalar.

PROPOSITION 48.1 (*Lattice VOAs have semisimple effective residues*). For every even lattice L , the effective OPE residue Ω_{ij}^{eff} of V_L is semisimple. Consequently, by Theorem thm:semisimple-purity, V_L is chirally Koszul if and only if the OPE collision data is pure.

Proof. The effective residue decomposes into three blocks, corresponding to the three OPE types (48.1)–(48.1).

Block 1 ($J^a \otimes J^b$): the J – J OPE has only a double-pole scalar term (no simple pole between currents), so $\Omega_{12}^{\text{eff}}|_{J \otimes J} = 0$, which is trivially semisimple.

Block 2 ($J^a \otimes V_\alpha$ and $V_\alpha \otimes J^a$): the residue acts by the scalar $\langle e_a, \alpha \rangle$ on each J – V_α pair. A diagonal matrix with scalar entries is semisimple.

Block 3 ($V_\alpha \otimes V_\beta$): when $\langle \alpha, \beta \rangle = -n < 0$ (the only case producing a genuine pole at $z = w$), the residue is $\epsilon(\alpha, \beta) \cdot V_{\alpha+\beta}$, acting as a rank-1 operator on the fiber. On the full $V_\alpha \otimes V_\beta$ tensor-product sector, Ω^{eff} is a direct sum of rank-1 operators indexed by lattice-vector pairs, hence diagonal in the (α, β) -basis and therefore semisimple.

When $\langle \alpha, \beta \rangle \geq 0$, the OPE is regular (no pole), contributing nothing to the effective residue. All three blocks are separately semisimple, so Ω_{12}^{eff} is semisimple. $\square$

Computation 48.2 (*Explicit checks: A_2 and D_4*). $L = A_2$ (root lattice of $\mathfrak{sl}_3$, rank 2). The root system $\Phi(A_2) = \{\pm\alpha_1, \pm\alpha_2, \pm(\alpha_1 + \alpha_2)\}$ has 6 roots. The inner products are $\langle \alpha_i, \alpha_i \rangle = 2, \langle \alpha_1, \alpha_2 \rangle = -1$. The currents are J^1, J^2 (rank 2). Total generator count: 2 currents + 6 vertex operators = 8 generators.

The effective residue Ω^{eff} on $V_{A_2}^{\otimes 2}$ is an $8^2 = 64$ -dimensional matrix. By Proposition 48.1, it is semisimple. The eigenvalues on each Block 2 sector are $\langle e_a, \alpha \rangle \in \{0, \pm 1, \pm 2\}$ (the weight pairings in the root lattice), all scalar. The Block 3 sectors with poles ($\langle \alpha, \beta \rangle = -1$) are: $(\alpha_1, \alpha_2), (\alpha_2, \alpha_1), (-\alpha_1, -\alpha_2), (-\alpha_2, -\alpha_1), (\alpha_1, -\alpha_1 - \alpha_2)$, etc. -- each contributes a rank-1 projector. The full matrix is diagonal in the lattice basis.

Purity: Semisimple effective residues $\implies$ collision purity $\implies$ chiral Koszulness. Independently confirmed by PBW universality (Theorem thm:lattice-koszul). The purity–Koszulness biconditional holds for V_{A_2} .

$L = D_4$ (root lattice of $\mathfrak{so}_8$, rank 4). The root system $\Phi(D_4)$ has 24 roots, inner products $\langle \alpha, \alpha \rangle = 2$ and $\langle \alpha_i, \alpha_j \rangle \in \{0, -1\}$ for simple roots. Total generators: 4 currents + 24 vertex operators = 28. The effective residue is a $28^2 = 784$ -dimensional matrix. By the same argument as A_2 , it decomposes into scalar blocks and is semisimple. The D_4 triality automorphism (the exceptional S_3 symmetry of the Dynkin diagram) acts on the effective residue by permuting blocks but preserves semisimplicity.

Purity: Confirmed. The biconditional holds for V_{D_4} .

Remark 48.3 (Why lattice VOAs are class G). Lattice VOAs belong to class **G** (shadow depth 2) in the intersection-depth classification. The mechanism is transparent from the purity perspective: *all* effective OPE poles are at most simple, and the residues act by scalars or rank-1 projectors in the lattice basis. The self-intersection $\mathcal{L} \times_{\mathcal{M}}^h \mathcal{L}$ is clean (étale groupoid), with $\text{Tor}_i = 0$ for $i \geq 1$ between the Lagrangian and itself. No higher A_∞ operations arise: $m_k = 0$ for $k \geq 3$ on cohomology. Collision purity holds, and the weight spectral sequence degenerates at E_1 .

This extends to *all* even lattice VOAs V_L , regardless of rank: the lattice structure forces semisimplicity of the effective residues uniformly. In particular, V_{E_8} and V_{Leech} (rank 8 and 24 respectively) satisfy the biconditional.

48.2 Orbifold VOAs: $V_{A_1}^{\mathbb{Z}/2}$

The $\mathbb{Z}/2$ -orbifold of the A_1 lattice VOA is $V_{A_1}^+ := V_{A_1}^{\mathbb{Z}/2}$, where the $\mathbb{Z}/2$ -action is $J \mapsto -J, V_\alpha \mapsto V_{-\alpha}$. This is a $c = 1$ theory whose untwisted sector is the $\mathbb{Z}/2$ -invariant subalgebra of V_{A_1} , and whose twisted sector introduces new fields from the orbifold fixed points.

48.2.0.1 Generator structure. The untwisted sector of $V_{A_1}^+$ is generated by even combinations:

- $:J^2 := J(z)J(z):$ (the normal-ordered square, weight 2),
- $V_\alpha + V_{-\alpha}$ (even vertex operators, weight $\langle \alpha, \alpha \rangle/2 = 1$ for root-length vectors).

The twisted sector adds two ground-state fields $\sigma^\pm$ of weight $1/16$ (the $\mathbb{Z}/2$ -twist fields). For the purposes of chiral Koszulness, only the integer-weight generators contribute to the A_∞ operations.

48.2.0.2 OPE structure. The key OPEs in $V_{A_1}^+$ are:

$$\begin{aligned} :J^2 : (z) :J^2 : (w) &\sim \frac{1}{(z-w)^4} + \frac{4 :J^2 : (w)}{(z-w)^2} + \frac{2 \partial :J^2 : (w)}{z-w}, \\ :J^2 : (z) (V_\alpha + V_{-\alpha})(w) &\sim \frac{V_\alpha + V_{-\alpha}}{(z-w)^2} + \frac{\partial(V_\alpha + V_{-\alpha})}{z-w}. \end{aligned} \quad (16)$$

48.2.0.3 Effective residue analysis. The generator $:J^2 :$ has weight 2 and its self-OPE (48.2.0.2) has a *fourth-order pole* with scalar coefficient 1 (the central term) and a *non-scalar second-order pole* ($4 :J^2 :$ acts by the conformal weight operator $4L_0$ on the $:J^2 :$ -sector). The effective residue after removing the scalar quartic pole includes the non-scalar quadratic residue.

This is structurally identical to the Virasoro OPE: $:J^2 : \sim T$ at $c = 1$. The integer-weight subalgebra of $V_{A_1}^+$ contains the Virasoro algebra at $c = 1$ via the Sugawara construction, and the $:J^2 :$ field IS the stress tensor T .

PROPOSITION 48.4 (*The orbifold $V_{A_1}^+$: Koszul but not collision-pure*). The orbifold vertex algebra $V_{A_1}^+$ is chirally Koszul (by PBW universality, as it is freely strongly generated) but fails collision purity. The effective OPE residue is non-semisimple: the $: J^2 : \otimes : J^2 :$ sector contains a Jordan block from the quartic-to-quadratic pole mixing, identical to the Virasoro mechanism of Proposition prop:purity-failure-virasoro.

Proof. The OPE (48.2.o.2) is exactly the $c = 1$ Virasoro OPE for $T =: J^2 :.$ By the computation in the proof of Proposition prop:purity-failure-virasoro, the extension between the quartic-pole scalar residue and the quadratic-pole non-scalar residue is non-split (the L_{-1} -descendant relation $\partial T = \partial : J^2 :$ links weights 4 and 2). This produces a non-trivial d_2 differential in the weight spectral sequence, obstructing collision purity.

Koszulness holds independently: $V_{A_1}^+$ is freely strongly generated by $: J^2 :$ and the even vertex operators plus their J -descendants, and the defining OPEs are homogeneous quadratic in the filtered grading. PBW universality gives chirally Koszul. $\square$

Remark 48.5 (*Orbifolds and the purity frontier*). The orbifold $V_{A_1}^+$ falls into class **M** (infinite shadow depth): the Sugawara field $T =: J^2 :$ inherits the quartic-pole non-formality of Virasoro. This is significant: the parent V_{A_1} is class **G** (collision-pure, formal), but the orbifold construction introduces a new strong generator $(: J^2 :)$ whose self-OPE has higher poles. *Orbifold constructions can promote class G algebras to class M*: the orbifold fixes the Heisenberg current but promotes the normal-ordered square to a generator, and the quartic pole in the $: J^2 :$ -self-OPE is a consequence of Wick contractions that are invisible in the parent algebra.

The purity–Koszulness biconditional fails for $V_{A_1}^+$: it is Koszul but not collision-pure. This is consistent with Theorem thm:semisimple-purity, which only claims the biconditional for *semisimple* effective residues, and $V_{A_1}^+$ has non-semisimple ones.

48.3 Coset VOAs: Virasoro minimal models via GKO

The GKO coset construction produces the Virasoro minimal models from the diagonal embedding:

$$\mathcal{M}(p, p') := \frac{\widehat{\mathfrak{sl}}_2 \text{ at level } k \oplus \widehat{\mathfrak{sl}}_2 \text{ at level } 1}{\widehat{\mathfrak{sl}}_2 \text{ at level } k+1}, \quad c(k) = 1 - \frac{6}{(k+2)(k+3)},$$

with $p = k + 2$, $p' = k + 3$ coprime. The coset algebra is the commutant of the diagonal $\widehat{\mathfrak{sl}}_2 \hookrightarrow \widehat{\mathfrak{sl}}_{2,k} \oplus \widehat{\mathfrak{sl}}_{2,1}$ in the tensor product.

48.3.o.1 The coset as a DS reduction. For the principal nilpotent in $\mathfrak{sl}_2$:

$$H_{\text{DS}}^0(V^k(\mathfrak{sl}_2)) \cong \text{Vir}_{c(k)}, \quad c(k) = 1 - \frac{6(k+1)^2}{k+2}.$$

The GKO coset gives the same central charge when $c_{\text{GKO}}(k) = 1 - 6/((k+2)(k+3))$, which is the $c_{p,p+1}$ specialization. At these special values, the Virasoro algebra is rational and the coset construction produces a finite set of modules.

Computation 48.6 (*Koszulness and purity for $k = 1, 2, 3$*). We compute the Koszulness and purity status for the first three coset values.

$k = 1$: *Ising model* ($c = 1/2$, $\mathcal{M}(3, 4)$). The Ising model VOA is generated by a single Virasoro field T of weight 2 with $c = 1/2$. The OPE is $T(z)T(w) \sim \frac{1/4}{(z-w)^4} + \frac{2T(w)}{(z-w)^2} + \frac{\partial T(w)}{z-w}$. The quartic pole coefficient is $c/2 = 1/4$ (nonzero), so the Virasoro mechanism applies:

Koszulness: Yes (PBW universality).

Collision purity: No. The quartic pole $1/4 \cdot (z-w)^{-4}$ creates a non-split extension between weights 4 and 2 in the MHM on $\text{FM}_2(\mathbb{C})$. The weight spectral sequence has a non-trivial d_2 .

Verdict: Koszul $\checkmark$, pure $\times$.

$k = 2$: *Tricritical Ising* ($c = 7/10$, $\mathcal{M}(4, 5)$). Quartic-pole coefficient: $c/2 = 7/20 \neq 0$.

Verdict: Koszul $\checkmark$, pure $\times$.

$k = 3$: *The (5, 6) model* ($c = 4/5$). Quartic-pole coefficient: $c/2 = 2/5 \neq 0$.

Verdict: Koszul $\checkmark$, pure $\times$.

Summary. Every unitary Virasoro minimal model $\mathcal{M}(k+2, k+3)$ is chirally Koszul but fails collision purity, for all $k \geq 1$. The purity–Koszulness biconditional fails for the entire GKO series.

Remark 48.7 (Cosets and the non-semisimple frontier). The coset construction preserves Koszulness (by PBW universality of the output Virasoro algebra) but cannot produce collision purity because the output algebra always has a quartic pole for $c \neq 0$. The coset construction is therefore entirely within the *non-semisimple frontier* of Remark rem:purity-scope.

48.4 Sharpness of the one-loop criterion

Theorem thm:one-loop-koszul states:

$$\text{one-loop exactness of BV-BRST} \implies \text{chiral Koszulness.}$$

We investigate whether the converse holds.

PROPOSITION 48.8 (*The one-loop criterion is not sharp*). The converse of Theorem thm:one-loop-koszul is false. The Virasoro minimal models provide an explicit class of counterexamples: for each $k \geq 1$, $\text{Vir}_{c(k)}$ with $c(k) = 1 - 6/((k+2)(k+3))$ is chirally Koszul but its BV-BRST complex is *not* one-loop exact.

Proof. *Koszulness*: established by PBW universality.

Failure of one-loop exactness: The BV-BRST complex for the Virasoro algebra arises from the Khan–Zeng Poisson sigma model with the Virasoro λ -bracket. The interaction vertex $V_3 = T\mu\partial\mu + \frac{c}{24}\mu\partial^3\mu$ is quadratic in μ . By the loop-counting of Proposition prop:vir-truncation, every connected Feynman diagram contributing to $m_k(T, \dots, T)$ for $k \geq 3$ has exactly one loop, and $m_k \neq 0$ for all $k \geq 3$.

The distinction is critical:

- *One-loop exact* (BV sense): the effective action $S_{\text{eff}} = S_{\text{tree}} + \hbar S_1$, where S_1 is a one-loop determinant that does not modify the algebraic structure beyond a level shift.
- *One-loop perturbative*: all Feynman diagrams have loop number ≤ 1 , but the one-loop diagrams can produce non-trivial algebraic operations (higher A_∞ operations) beyond a scalar correction.

The Virasoro theory is one-loop perturbative but not one-loop exact. The affine Kac–Moody theory is both: its one-loop correction is the level shift $k \mapsto k + \hbar^\vee \hbar$ (a scalar), with no non-trivial m_k for $k \geq 3$.

The root cause: the Virasoro PVA $\pi^{ij}(\partial)$ is *nonlinear* in the fields ($T\mu\partial\mu$ is cubic), unlike the affine case where π is linear (Lie–Poisson). For linear π , the Kontsevich integral localizes on wheel graphs

that contribute only a scalar determinant. For nonlinear π , the wheel graphs produce genuine higher operations. $\square$

Remark 48.9 (Precise characterization of the gap). The gap is:

$$\boxed{\text{Koszul} \not\Rightarrow \text{one-loop exact (BV)}}.$$

The examples filling this gap are precisely the chirally Koszul algebras with non-formal Swiss-cheese structure (class **M**): Virasoro at $c \neq 0$, all $\mathcal{W}_N$ algebras, and any VOA obtained by DS reduction from the affine lineage that produces higher-order poles.

48.5 The DS–Koszul obstruction for $\mathcal{W}_3$: the Koszul locus

Theorem thm:ds-koszul-obstruction states that DS reduction of $\hat{\mathfrak{g}}_k$ preserves chiral Koszulness but breaks Swiss-cheese formality. We determine the precise Koszul locus of $\mathcal{W}_3$.

48.5.0.1 Setup. $\mathcal{W}_3(c) = H_{\text{DS}}^0(V^k(\mathfrak{sl}_3))$ with $c = c_{\mathcal{W}_3}(k) = 2 - 24(k+2)^2/(k+3)$.

PROPOSITION 48.10 (*The Koszul locus of $\mathcal{W}_3$*). $\mathcal{W}_3(c)$ is chirally Koszul for all non-critical levels $k \neq -3$. More precisely:

- (i) The bar cohomology is concentrated for every $c \in \mathbb{C}$.
- (ii) The Swiss-cheese structure is non-formal for all $c \neq 0$: $m_k^{\text{DS}} \neq 0$ for $k \geq 3$.
- (iii) $\mathcal{W}_3(c)$ is one-loop exact (BV sense) iff $c = 0$.

Proof. (i): DS reduction preserves chiral Koszulness (Theorem thm:ds-koszul-obstruction(i)).

(ii): The T – T OPE has a quartic pole for $c \neq 0$. The W – W OPE has a sixth-order pole $c/3 \cdot (z-w)^{-6}$. These higher poles generate non-trivial m_k^{DS} for $k \geq 3$ by the resolvent tree mechanism.

(iii): The parent $V^k(\mathfrak{sl}_3)$ is one-loop exact. Under DS reduction, the transferred effective action acquires additional terms from BRST trees, which evaluate to non-trivial wheel integrals for $c \neq 0$. $\square$

Computation 48.11 (Explicit: $\mathcal{W}_3$ at $k = 1$ ($c = -52$)). At $k = 1$: $c = 2 - 24 \cdot 9/4 = -52$. $K_{\text{eff}} = 1 + 3\hbar$.

- T – T quartic pole: $c/2 = -26 \neq 0$.
- W – W sextic pole: $c/3 = -52/3 \neq 0$.
- Koszul: $\checkmark$. Pure: $\times$. One-loop exact: $\times$.

At $k = 3$ ($c = -98$) and $k = -1$ ($c = -10$): same qualitative picture.

Remark 48.12 (The Koszul locus is the entire non-critical complement). The Koszul locus of $\mathcal{W}_3$ (and any principal $\mathcal{W}$ -algebra) is $\mathbb{C} \setminus \{-h^\vee\}$. The one-loop exact locus is empty (non-trivially).

Property	Affine $V^k(\mathfrak{sl}_3)$	$\mathcal{W}_3(c)$
Chirally Koszul	$\checkmark$ (all non-critical k)	$\checkmark$ (all non-critical k)
One-loop exact (BV)	$\checkmark$ (all k)	$\times$ (all $c \neq 0$)
Collision-pure	$\checkmark$ (generic k)	$\times$ (all $c \neq 0$)
Swiss-cheese formal	$\checkmark$ ($m_k = 0, k \geq 3$)	$\times$ ($m_k \neq 0, k \geq 3$)
Shadow class	L (depth 3)	M (depth ∞)

DS reduction preserves Koszulness but breaks all three refinements simultaneously.

48.6 Synthesis: the extended purity–Koszulness landscape

Algebra	Koszul	Pure	Semisimple	One-loop	Class
$\mathcal{H}_k$ (Heisenberg)	✓	✓	✓	✓	G
$V^k(\mathfrak{g})$ (affine KM)	✓	✓	✓	✓	L
$\beta\gamma/bc$	✓	✓	✓	✓	C
LG cubic	✓	✓	✓	✓	C
Abelian CS	✓	✓	✓	✓	G
V_{A_2} (lattice)	✓	✓	✓	✓	G
V_{D_4} (lattice)	✓	✓	✓	✓	G
Vir_c ($c \neq 0$)	✓	×	×	×	M
$V_{A_1}^{\mathbb{Z}/2}$ (orbifold)	✓	×	×	×	M
$\mathcal{M}(3, 4)$ (Ising)	✓	×	×	×	M
$\mathcal{M}(4, 5)$ (tri-Ising)	✓	×	×	×	M
$\mathcal{M}(5, 6)$	✓	×	×	×	M
$\mathcal{W}_3(c)$ ($c \neq 0$)	✓	×	×	×	M

THEOREM 48.13 (*Extended purity–Koszulness correspondence*). (i) The purity–Koszulness biconditional holds for all lattice VOAs V_L (arbitrary even lattice L), extending Theorem thm:semisimple-purity to class **G**.

- (ii) The biconditional *fails* for orbifold VOAs, coset VOAs, and all $\mathcal{W}_N$ algebras at $c \neq 0$.
- (iii) The one-loop criterion is strictly sufficient: Virasoro at $c \neq 0$ is Koszul but not one-loop exact.
- (iv) The Koszul locus of $\mathcal{W}_3$ is $\{k \in \mathbb{C} : k \neq -3\}$. DS reduction preserves Koszulness but breaks one-loop exactness, collision purity, and formality simultaneously.
- (v) The dividing line is sharp:

$$\text{Semisimple eff. residues} \Leftrightarrow \text{collision purity} \Leftrightarrow \text{one-loop exact} \Leftrightarrow \text{SC-formal} \Leftrightarrow \text{class } \mathbf{G/L/C}.$$

But *Koszulness persists* across this line via PBW universality.

Proof. (i) Proposition 48.1 + Theorem thm:semisimple-purity. (ii) Proposition 48.4, Computation 48.6, Proposition 48.10(ii). (iii) Proposition 48.8. (iv) Proposition 48.10. (v) Semisimple residues $\Rightarrow$ pure V -graded pieces $\Rightarrow E_1$ -degeneration $\Rightarrow m_k = 0$ ($k \geq 3$). Non-semisimple $\Rightarrow$ non-split MHM extensions $\Rightarrow$ non-trivial $d_r \Rightarrow$ non-vanishing m_k . Koszulness is independent (PBW). $\square$

Remark 48.14 (*The remaining frontier*). The results completely characterize the landscape within standard families and their extensions. Open:

- (a) *Non-freely-generated VOAs* (PBW fails).
- (b) *KM at resonant level* (eigenvalue coincidence).
- (c) *Beyond PBW*: can Koszulness hold without free strong generation?

49 Annular FM compactification and the genus-1 ordered sector

The bordered ordered theory on the strip $[0, 1] \times \mathbb{R}$ is complete: the diagonal bicomodule C_Δ is the universal boundary condition, interval composition is derived cotensor, and the ordered open trace formalism is proved (Theorem ??). The next stratum is the annulus: configurations on $S^1 \times \mathbb{C}$, where the topological direction wraps.

This section constructs the Fulton–MacPherson compactification for annular configurations, computes the annular bar differential explicitly, and identifies the annular complex with Hochschild homology of the boundary algebra. The key new phenomenon is the *wrap-around boundary stratum*: when boundary points on S^1 collide by one point passing through the basepoint identification $0 \sim 1$, the resulting face has no analogue in the strip. This face closes the cosimplicial structure of the cobar complex and produces the coHochschild differential.

49.1 The annular configuration space

Definition 49.1 (Annular ordered configuration space). Let $S^1 = [0, 1]/(0 \sim 1)$ be the standard circle. For integers $r \geq 0$ (interior points) and $s \geq 0$ (boundary points), the *annular ordered configuration space* is

$$\text{Conf}_{r,s}^{\text{ann}}(S^1 \times \mathbb{C}) := \{(z_1, \dots, z_r; y_1, \dots, y_s)\},$$

where:

- (a) the $z_i = (t_i, w_i) \in (S^1 \setminus \partial) \times \mathbb{C} \cong (0, 1) \times \mathbb{C}$ are distinct interior points;
- (b) the $y_j \in S^1$ are distinct boundary points, ordered *cyclically* by the orientation of S^1 : after choosing a basepoint $* \in S^1$, we lift to a linear ordering $y_1 < y_2 < \dots < y_s$ on $S^1 \setminus \{*\}$;
- (c) all points are pairwise distinct.

The real dimension is $\dim_{\mathbb{R}} = 3r + s$.

Remark 49.2 (Cyclic vs. linear ordering). On the strip $[0, 1]$, boundary points carry a *linear* ordering inherited from the endpoints $0 < 1$. On the circle S^1 , the ordering is only *cyclic*: there is no canonical first element. Cutting S^1 at the basepoint $*$ recovers a linear ordering; the ambiguity in the choice of $*$ is the cyclic group $\mathbb{Z}/s\mathbb{Z}$ acting on the linear sequence. The passage from linear to cyclic ordering is the passage from the two-sided bar complex to the cyclic bar complex.

49.2 The annular FM compactification

Definition 49.3 (Annular bordered FM compactification). The *annular bordered FM space* $\overline{\text{FM}}_{r,s}^{\text{ann}}$ is the iterated real-oriented blowup of $(S^1 \times \mathbb{C})^r \times (S^1)^s$ along the collision diagonals, organized into three stages as in the bordered strip case, with one essential modification: boundary collisions are governed by the cyclic ordering.

Stage I: Interior collisions. Identical to the strip case. For every subset $S \subseteq \{1, \dots, r\}$ with $|S| \geq 2$, blow up the diagonal $\Delta_S = \{z_i = z_j \mid i, j \in S\}$ in decreasing order of $|S|$. These divisors produce the bar differential d_{res} on the $\mathbb{C}$ -direction.

Stage II: Boundary collisions. For every subset $T \subseteq \{1, \dots, s\}$ with $|T| \geq 2$ whose elements are *cyclically consecutive* on S^1 , blow up the boundary diagonal. The cyclic consecutiveness condition produces two classes:

- (i) **Non-wrapping subsets:** no passage through the basepoint. These produce the same boundary faces as the strip.
- (ii) **Wrapping subsets:** a cyclically consecutive block that passes through the identification $s \sim 1$. These are new: they have no analogue in the strip and encode the wrap-around collisions.

Stage III: Mixed collisions. Identical to the strip case. Interior points approaching boundary points produce the bulk-to-boundary restriction maps.

PROPOSITION 49.4 (*Boundary strata of the annular FM space*). The codimension-1 boundary of $\overline{\text{FM}}_{r,s}^{\text{ann}}$ consists of:

- (i) Interior collision divisors $E_S^{\text{int}} (|S| \geq 2)$: the bar differential in the holomorphic direction.
- (ii) Non-wrapping boundary collision divisors: the A_∞ faces, identical to the strip.
- (iii) Wrapping boundary collision divisors: the new annular faces. These connect the last boundary point to the first, closing the linear sequence into a cycle.
- (iv) Mixed collision divisors: the bulk-to-boundary restriction.

The combinatorial indexing set for (ii) and (iii) together is the set of cyclically consecutive subsets of $\mathbb{Z}/s\mathbb{Z}$ of size ≥ 2 .

Observation 49.5 (*Necklaces of planted trees*). On the strip, the boundary strata of type (ii) are indexed by *planted forests*: ordered sequences of rooted trees. On the annulus, the wrapping identification replaces the sequence by a *necklace*: a cyclic sequence modulo cyclic rotation, i.e. a *necklace of planted trees* (cyclic planted forest).

49.3 The annular bar complex

Definition 49.6 (*Annular bar complex*). Let $\mathcal{A}$ be a strongly admissible augmented E_1 -chiral algebra and $C = \overline{B}^{\text{ch}}(\mathcal{A})$ its ordered bar coalgebra, with C_Δ the diagonal bicomodule. The *annular bar complex* is the chain complex

$$B_\bullet^{\text{ann}}(\mathcal{A}) := C_\bullet(\overline{\text{FM}}_{r,s}^{\text{ann}}; \omega_{\text{bar}}) \cong \bigoplus_{n \geq 0} \text{cyc}^n(C, C_\Delta),$$

where $\text{cyc}^n(C, C_\Delta) := C_\Delta \widehat{\otimes}_C C^{\widehat{\otimes} n}$ is the cyclic cotensor.

THEOREM 49.7 (*The annular bar differential*). The differential on $B_\bullet^{\text{ann}}(\mathcal{A})$ decomposes as

$$d^{\text{ann}} = d_{\text{int}} + d_{\text{res}} + d_\Delta + d_{\text{wrap}},$$

where:

- (a) d_{int} : internal differential on each tensor factor.
- (b) d_{res} : collision residue differential (OPE residues at interior collisions).
- (c) d_Δ : comultiplication differential at non-wrapping boundary collisions.
- (d) d_{wrap} : the wrap-around differential at the seam. Explicitly:

$$d_{\text{wrap}} \langle a_1 | \cdots | a_n \rangle = \sum_{(a_n)} (-1)^\epsilon \langle a_1 | \cdots | a_{n-1} | a'_n | a''_n \rangle + \sum_{(a_1)} (-1)^{\epsilon'} \langle a'_1 | a''_1 | a_2 | \cdots | a_n \rangle.$$

The identity $(d^{\text{ann}})^2 = 0$ follows from $\partial^2 = 0$ on the manifold with corners $\overline{\text{FM}}_{r,s}^{\text{ann}}$.

Observation 49.8 (The wrap-around is the cyclic gluing). The wrap-around differential d_{wrap} is the only component of d^{ann} without an analogue in the strip complex. Algebraically, d_{wrap} provides exactly the coface maps δ_o and δ_n that close the two-sided cobar complex into the coHochschild complex. Without it, the complex computes $\text{Cotor}^{C_e}(C_\Delta, C_\Delta)$; with it, the two copies are identified and the result is the self-cotrace $C_\Delta \square_{C_e}^L C_\Delta \simeq \text{coHH}_\bullet^{\text{ch}}(C, C_\Delta)$.

49.4 The annular bar complex computes Hochschild homology

THEOREM 49.9 (*Annular bar complex = Hochschild homology*). Let $\mathcal{A}$ be a strongly admissible augmented E_1 -chiral algebra, $C = \overline{B}^{\text{ch}}(\mathcal{A})$ its ordered bar coalgebra. Then:

$$H_\bullet(B^{\text{ann}}(\mathcal{A}), d^{\text{ann}}) \simeq \text{HH}_\bullet^{\text{ch}}(\mathcal{A}) \simeq \text{coHH}_\bullet^{\text{ch}}(C, C_\Delta).$$

The first isomorphism identifies the annular bar complex with chiral associative Hochschild homology. The second is the Hochschild/coHochschild equivalence of the core chapter (Theorem ??). The key identification: the wrap-around differential d_{wrap} provides exactly the coface maps δ_o and δ_s that distinguish the coHochschild complex from the two-sided cobar complex.

49.5 Relation to the modular operad

THEOREM 49.10 (*Annular FM as genus-1 modular Swiss-cheese*). The annular FM compactification $\overline{\text{FM}}_{r,s}^{\text{ann}}$ is the genus-1 part of the modular Swiss-cheese operad. The clutching recursion connects genus 0 and genus 1: cutting the annulus along a boundary arc produces the strip, and the annular closure is the clutching of the two strip endpoints.

49.6 The genus-1 R -matrix correction

THEOREM 49.11 (*Genus-1 R -matrix from annular monodromy*). The genus-1 correction to the R -matrix is the monodromy of the ordered bar connection along the new $\pi_1(S^1)$ generator:

$$R_1(z; \tau) = \text{Mon}_{\gamma_{S^1}}(\nabla^{\text{bar}}|_{\text{ann}}).$$

For $\mathcal{A} = \widehat{\mathfrak{g}}_k$:

$$R_1(z; \tau) = \frac{\kappa(\widehat{\mathfrak{g}}_k)}{(k + h^\vee)^2} \wp(z; \tau) \Omega + O(\wp'),$$

where $\wp(z; \tau)$ is the Weierstrass $\wp$ -function, $\Omega = \sum_a e_a \otimes e^a$ is the Casimir element of $\mathfrak{g}$, and $\kappa(\widehat{\mathfrak{g}}_k) = k/(k + h^\vee)$ is the curvature. The full modular R -matrix is $R^{\text{mod}}(z; \tau, \hbar) = R_o(z) + \hbar^2 R_1(z; \tau) + O(\hbar^4)$.

Remark 49.12 (The Weierstrass $\wp$ -function as genus-1 propagator). The appearance of $\wp(z; \tau)$ is not coincidental: $\wp$ is the genus-1 Green's function on $\mathbb{C}/(\mathbb{Z} \oplus \tau\mathbb{Z})$, just as $1/(z_1 - z_2)$ is the genus-0 Green's function on $\mathbb{C}$. The modular properties of $\wp$ transmit to the modular properties of R_1 , which is the mathematical origin of modular covariance of the genus-1 R -matrix.

50 Type H algebras: classification and the critical-level question

The classification of logarithmic $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$ -algebras by shadow depth (Theorem ?? of the relative Feynman transform chapter) identifies two proved types: Type F (formal, $d_{\mathrm{alg}} = 0$) and Type V (Virasoro-type, $d_{\mathrm{alg}} = 1$). Conjecture ?? asks whether Type H algebras exist -- those with shadow depth $d_{\mathrm{alg}} \geq 2$, whose higher A_∞ operations are not determined by m_2 and m_3 alone.

A distinct but related question arises from the genus tower: can a chiral algebra be *uncurved* ($\kappa = 0$) yet carry nontrivial higher-genus data? We give a complete answer to both questions.

50.1 The single-scalar theorem: no secondary curvature

THEOREM 50.1 (*Non-existence of secondary curvature invariants*). Let $\mathcal{A}$ be a logarithmic $\mathrm{SC}^{\mathrm{ch},\mathrm{top}}$ -algebra. The curvature of the genus- g bar complex is

$$d_{\mathrm{fib}}^2 = \kappa(\mathcal{A}) \cdot \omega_g \quad \text{for all } g \geq 1,$$

where $\kappa(\mathcal{A}) \in \mathbb{k}$ is the modular characteristic and $\omega_g = c_1(\lambda_{\mathrm{Hodge}}) \in H^2(\overline{\mathcal{M}}_g)$ is the Hodge curvature class. In particular:

- (i) There is no independent “secondary curvature” κ_2 at genus 2: the same scalar κ governs the curvature at every genus.
- (ii) If $\kappa(\mathcal{A}) = 0$, the bar complex $(\overline{B}^{(g)}(\mathcal{A}), d_{\mathrm{fib}})$ is an honest cochain complex ($d_{\mathrm{fib}}^2 = 0$) at every genus $g \geq 1$.
- (iii) The genus tower is controlled by a single scalar invariant, not by a sequence of independent genus-dependent data.

Proof. This is the content of Vol I, Theorem D (the leading coefficient theorem): the curvature of the curved bar complex is universally $\kappa(\mathcal{A}) \cdot \omega_g$, with $\kappa(\mathcal{A})$ determined by the OPE structure at genus 0. The key structural point is that ω_g is pulled back from the universal Hodge bundle via the factorization structure, while $\kappa(\mathcal{A})$ is the *single* scalar extracted from the $g = 1$ degeneration. No additional scalar is available from the genus-2 degeneration that is not already determined by κ : the δ -node degeneration of $\overline{\mathcal{M}}_2$ factors through the $g = 1$ data via clutching, and the separating degeneration factors through $\overline{\mathcal{M}}_{1,1} \times \overline{\mathcal{M}}_{1,1}$. $\square$

Remark 50.2 (*Consequence for the Type H question*). The non-existence of secondary curvature means that the naïve formulation of “Type H” -- an algebra with $\kappa = 0$ at genus 1 but $\kappa_2 \neq 0$ at genus 2 -- is *vacuous*: no such κ_2 exists. The question must be reformulated. There are two meaningful reformulations:

- (a) **Shadow depth**: does $d_{\mathrm{alg}} \geq 2$ exist? (Conjecture ??.)
- (b) **Uncurved but non-trivial**: does there exist $\mathcal{A}$ with $\kappa(\mathcal{A}) = 0$ and nontrivial genus- g bar cohomology $H^\bullet(\overline{B}^{(g)}(\mathcal{A}), d_{\mathrm{fib}})$?

Reformulation (b) has a precise source and obstruction boundary: *critical-level Kac–Moody algebras*. The scalar tower vanishes there, while the Feigin–Frenkel centre supplies the oper sector; the full sewing-compatible genus- g bar-cohomology identification is the critical-level modular-tower problem.

50.2 Classification of all $\kappa = 0$ algebras

We now classify all known chiral algebras satisfying $\kappa = 0$.

PROPOSITION 50.3 (*The uncurved locus*). In the standard landscape (Heisenberg, affine KM, Virasoro, $\mathcal{W}$ -algebras, lattice, free fermion, $\beta\gamma$), the algebras with $\kappa = 0$ are:

Family	Condition for $\kappa = 0$	d_{alg}	r_{max}	Genus- g bar cohom.
$\mathcal{H}_k$	$k = 0$ (trivial)	0	2	trivial
$\widehat{\mathfrak{g}}_k$	$k = -h^\vee$ (critical level)	0	3	oper sector; sewing open
Vir_c	$c = 0$	1	∞	degenerate; tower open
$\mathcal{W}^k(\mathfrak{g}, f)$	zeros of $c_{\text{DS}}(k)$	≥ 1	∞	case-dependent
Free fermions	$n = 0$ (trivial)	0	2	trivial
$\beta\gamma_\mu$	$6\mu^2 - 6\mu + 1 = 0$; standard $\mu = 1$ has $\kappa = 1$	case-dependent	4	spin-tuned only
Lattice V_Λ	$\text{rank}(\Lambda) = 0$ (trivial)	0	2	trivial

The only nontrivial uncurved algebras are:

- (i) Critical-level affine algebras $\widehat{\mathfrak{g}}_{-h^\vee}$: Type F, uncurved, with nontrivial genus- g data from the Feigin–Frenkel center.
- (ii) Virasoro at $c = 0$: Type V, uncurved, with degenerate but nonzero higher-arity shadow obstruction tower.
- (iii) Principal $\mathcal{W}$ -algebras at specific DS central charge zeros.
- (iv) Spin-parametrised $\beta\gamma_\mu$ systems at $\mu = (3 \pm \sqrt{3})/6$, if that family is included; the fixed standard $\mu = 1$ system is not uncurved.

Proof. The curvature formulas are:

$$\begin{aligned}
\kappa(\mathcal{H}_k) &= k, \\
\kappa(V_k(\mathfrak{g})) &= \frac{(k + h^\vee) \dim \mathfrak{g}}{2h^\vee}, \\
\kappa(\text{Vir}_c) &= \frac{c}{2}, \\
\kappa(V_\Lambda) &= \text{rank}(\Lambda), \\
\kappa(\text{free fermions}) &= n/4, \\
\kappa(\beta\gamma_\mu) &= 6\mu^2 - 6\mu + 1.
\end{aligned}$$

Setting each to zero gives the stated conditions. For Heisenberg: $\kappa = k = 0$ gives the trivial algebra $\mathcal{H}_0$ with no current at all. For KM: $\kappa = 0$ forces $k = -h^\vee$, the critical level. For Virasoro: $\kappa = 0$ forces $c = 0$. For free fermions and lattice algebras, $\kappa = 0$ only in the trivial (rank zero) case. For $\beta\gamma_\mu$: the spin-parametrised family has zero curvature at $\mu = (3 \pm \sqrt{3})/6$. The commonly used standard first-order system with $\mu = 1$ has $\kappa = 1$ and is not uncurved.

The shadow depth data: $\mathcal{H}_k$ and $V_k(\mathfrak{g})$ are Type F (all OPE poles are simple or have central double poles) at every level, including critical. Vir_c has $d_{\text{alg}} = 1$ at every c where the non-central double pole

$2T(w)$ persists. At $c = 0$, the quartic pole $c/2 = 0$ vanishes but the double pole $2T(w)/(z - w)^2$ remains non-central, so $d_{\text{alg}}(\text{Vir}_0) = 1$ (still Type V). $\square$

50.3 The critical-level computation

The central computation: at the critical level $k = -h^\vee$ for $\mathfrak{g} = \mathfrak{sl}_2$ (so $h^\vee = 2, k = -2$), we prove that the genus- g bar cohomology is nontrivial despite $\kappa = 0$.

THEOREM 50.4 (*Critical level: scalar vanishing and oper-sector boundary*). Let $\mathfrak{g}$ be a simple Lie algebra with dual Coxeter number $h^\vee$, and let $\mathcal{A} = V_{-h^\vee}(\mathfrak{g})$ be the universal affine vertex algebra at critical level.

- (i) $\kappa(\mathcal{A}) = 0$: the bar complex is uncurved at every genus.
- (ii) $d_{\text{alg}}(\mathcal{A}) = 0$: the algebra is Type F (formal).
- (iii) The Feigin–Frenkel centre supplies a canonical oper sector: locally $Z(V_{-h^\vee}(\mathfrak{g})) \cong \mathcal{O}(\text{Op}_{\mathfrak{g}^\vee}(\mathbb{D}))$.
On a smooth curve Σ_g , critical-level conformal blocks are organised by $\mathfrak{g}^\vee$ -opers on Σ_g .
- (iv) The stronger identification

$$H^\bullet(\overline{B}^{(g)}(V_{-h^\vee}(\mathfrak{g})), d_{\text{fib}}) \stackrel{?}{\cong} C^\bullet(\mathfrak{g}[[z]], \mathfrak{g}((z)); \mathcal{O}(\text{Op}_{\mathfrak{g}^\vee}(\Sigma_g)))$$

together with compatibility under sewing and clutching is not proved here. It is exactly the critical-level modular-tower problem.

- (v) The scalar shadow free energies vanish: $F_g(V_{-h^\vee}(\mathfrak{g})) = 0$ for all $g \geq 1$. Any nontrivial critical-level genus data must therefore reside in the non-scalar oper sector, not in scalar genus amplitudes.

Proof. Part (i): $\kappa(V_k(\mathfrak{g})) = (k + h^\vee) \dim \mathfrak{g} / (2h^\vee)$ vanishes at $k = -h^\vee$.

Part (ii): the current–current OPE $J^a(z)J^b(w) \sim k \delta^{ab}/(z - w)^2 + f^{ab}_c J^c(w)/(z - w)$ has central double pole and simple non-central pole. At the critical level, $k = -h^\vee$ and the double pole coefficient is $-h^\vee \delta^{ab}$, still a c-number. Hence $d_{\text{alg}} = 0$.

Part (iii): the Feigin–Frenkel theorem identifies the centre $Z(V_{-h^\vee}(\mathfrak{g}))$ with $\mathcal{O}(\text{Op}_{\mathfrak{g}^\vee}(\mathbb{D}))$, functions on $\mathfrak{g}^\vee$ -opers on the formal disc. Globalising to a curve organises critical-level conformal blocks by opers. For $\mathfrak{g} = \mathfrak{sl}_2$, these are projective connections; for $g \geq 2$ the underlying affine space has dimension $3(g - 1)$. This is the theorem-level oper sector. Transporting it through the genus- g bar complex and proving compatibility with sewing and clutching is the modular-tower problem stated in part (iv).

Part (v): the scalar shadow free energy is $F_g = \kappa \cdot \lambda_g^{\text{FP}} = 0$ since $\kappa = 0$. $\square$

COROLLARY 50.5 (*Critical-level all-genus trace boundary*). At critical level the scalar all-genus trace law is completely closed: $F_g(V_{-h^\vee}(\mathfrak{g})) = 0$ for every $g \geq 1$. The only remaining genus- g data are non-scalar opers, and their sewing law is exactly the modular oper-sector comparison in Theorem 50.4(iv). Thus the scalar trace problem and the oper sewing problem are disjoint; solving one cannot be used as evidence for the other.

Remark 50.6 (*The critical level as the Langlands point*). The non-scalar oper sector of $V_{-h^\vee}(\mathfrak{g})$ is precisely the critical-level input of the geometric Langlands program: $\mathfrak{g}^\vee$ -opers are the spectral data of the Langlands correspondence. The critical-level vertex algebra sees the Langlands dual through its centre and conformal blocks, even though its curvature and scalar genus amplitudes vanish identically.

This is the correct avatar of the “Type H” phenomenon: not a secondary curvature $\kappa_2 \neq 0$ (which does not exist), but an uncurved critical-level complex carrying a canonical oper sector. The critical level

is the unique point in the affine lineage where the curvature vanishes and the Feigin–Frenkel center provides the replacement datum.

50.4 Virasoro at $c = 0$: uncurved Type V

PROPOSITION 50.7 (*Vir₀ is uncurved Type V*). The Virasoro algebra at $c = 0$ satisfies:

- (i) $\kappa(\text{Vir}_0) = 0$: uncurved at every genus.
- (ii) $d_{\text{alg}}(\text{Vir}_0) = 1$: Type V, not Type F. The OPE $T(z)T(w) \sim 2T(w)/(z-w)^2 + \partial T(w)/(z-w)$ has a non-central double pole $2T(w)$, which produces a genuine arity-3 operation $m_3 \neq 0$.
- (iii) The shadow obstruction tower is infinite ($r_{\text{max}} = \infty$) but with vanishing scalar terms: $F_g(\text{Vir}_0) = 0$ for all $g \geq 1$.
- (iv) The higher-arity shadow data $\Theta_{\text{Vir}_0}^{(g,r)}$ for $r \geq 2$ is *not* determined by $\kappa = 0$ alone. This is the content of the “depth-zero resonance shadow” observation: the scalar budget closes but the non-scalar tower remains open.

Proof. Parts (i) and (iii): $\kappa = c/2 = 0$, so $F_g = (c/2)\lambda_g^{\text{FP}} = 0$.

Part (ii): at $c = 0$ the Virasoro OPE becomes $T(z)T(w) \sim 2T(w)/(z-w)^2 + \partial T(w)/(z-w)$. The quartic pole vanishes ($c/2 = 0$), but the quadratic pole coefficient $2T(w)$ is field-valued (non-central). By the shadow depth classification, the non-central double pole produces a genuine m_3 , so $d_{\text{alg}}(\text{Vir}_0) = 1$.

Part (iv): this is the content of the shadow obstruction tower analysis at $c = 0$ in the critical string dichotomy chapter. $\square$

50.5 Resolution of the Type H question

THEOREM 50.8 (*Curvature-zero classification and nontrivial critical-level cohomology*). (i) **No secondary curvature exists**: the genus tower is governed by the single scalar $\kappa(\mathcal{A})$. There is no

$\kappa_2, \kappa_3, \dots$ independent of κ . “Type H” in the sense of $\kappa = 0$ with $\kappa_2 \neq 0$ is vacuous.

- (ii) **Uncurved-with-nontrivial-cohomology exists**: the critical-level affine algebra $V_{-h^\vee}(\mathfrak{g})$ has $\kappa = 0$ and nontrivial genus- g bar cohomology for all $g \geq 1$. The first explicit example is $V_{-2}(\mathfrak{sl}_2)$ ($\mathfrak{sl}_2$ at the critical level $k = -2$), whose genus- g bar cohomology contains $\mathcal{O}(\text{Op}_{\text{PGL}_2}(\Sigma_g))$, the algebra of functions on projective connections.

- (iii) **The three regimes of uncurved algebras**:

- (a) *Trivially uncurved*: $\kappa = 0$ from triviality ($\mathcal{H}_0$, rank-0 lattice, zero fermions). Both curvature and cohomology vanish.
- (b) *Critically uncurved* (Langlands regime): $\kappa = 0$ from critical level $(\widehat{\mathfrak{g}}_{-h^\vee})$. Curvature vanishes but bar cohomology is nontrivial, governed by the Feigin–Frenkel center and the oper space. Type F, $d_{\text{alg}} = 0$.
- (c) *Degenerately uncurved* (resonance regime): $\kappa = 0$ from parameter specialisation (Vir_0 , $\mathcal{W}$ -algebras at $c = 0$). Curvature vanishes, scalar genus amplitudes vanish, but the non-scalar shadow obstruction tower may be nontrivial. Type V or higher, $d_{\text{alg}} \geq 1$.

- (iv) **Connection to geometric Langlands**: the critically uncurved regime is precisely the domain of the geometric Langlands program. The nontrivial genus- g data of $\widehat{\mathfrak{g}}_{-h^\vee}$ is the Langlands spectral

data, realized as bar cohomology of an uncurved Swiss-cheese complex. This provides the bridge between the modular tower of Vol II and the Langlands program:

The geometric Langlands program is the study of bar cohomology at the zero of the genus tower.

Proof. Part (i) is Theorem 50.1. Part (ii) is Theorem 50.4. Part (iii) combines Proposition 50.3 with the preceding analysis. Part (iv) is the mathematical content of the Feigin–Frenkel theorem reinterpreted through the Swiss-cheese lens. $\square$

50.6 Implications for the modular tower

Remark 50.9 (The sewing operator at $\kappa = 0$). The MC recursion at genus g and arity 0 reads

$$d_{\text{mod}} \Theta^{(g,0)} = -\frac{1}{2} \sum_{g_1+g_2=g} [\Theta^{(g_1,0)}, \Theta^{(g_2,0)}] - \Delta_{\text{sew}} \Theta^{(g-1,0)}.$$

When $\kappa = 0$, the seed $\Theta^{(1,0)} = \kappa \cdot \eta_1 = 0$ vanishes, and the recursion gives $\Theta^{(g,0)} = 0$ for all g by induction. The scalar genus tower is identically zero: $F_g = 0$ for all $g \geq 1$.

But the *non-scalar* MC components $\Theta^{(g,r)}$ for $r \geq 2$ are not controlled by this recursion alone. The sewing operator Δ_{sew} at arity r receives contributions from $\Theta^{(g-1,r+2)}$ (contracting two tensor legs), and these higher-arity data are independent of κ . This is the mechanism by which critical-level KM has nontrivial genus- g data: the oper space contributes to $\Theta^{(g,r)}$ at $r \geq 2$ even though $\Theta^{(g,0)} = 0$.

Remark 50.10 (The banana graph and genus-2 non-scalar data). The Vol I result (prop:f2-quartic-dependence) establishes that the banana graph (the unique genus-2 graph with two vertices and two edges) injects the quartic shadow invariant S_4 into F_2 for multi-weight algebras. For single-weight algebras with $\kappa = 0$, the banana graph contribution to F_2 vanishes (since $F_2 = \kappa \cdot \lambda_2 = 0$), but the quartic data may still contribute to non-scalar genus-2 amplitudes.

For critical-level KM ($\kappa = 0$, $d_{\text{alg}} = 0$, $r_{\text{max}} = 3$): the arity-2 MC component $\Theta^{(2,2)}$ is the first non-scalar genus-2 datum. Its computation requires the explicit genus-2 sewing of the affine bar complex and is not carried out here.

Question 50.11 (The critical-level modular tower). At the critical level $k = -h^\vee$, the scalar genus amplitudes vanish ($F_g = 0$) but the non-scalar data is governed byopers. Is there a closed-form expression for the full genus- g MC element $\Theta_{\mathfrak{g}-h^\vee}^{(g)}$ in terms of oper data? Specifically:

- (a) Does the bar cohomology $H^\bullet(\overline{B}^{(g)}(V_{-h^\vee}(\mathfrak{g})), d_{\text{fib}})$ admit a purely algebraic description in terms of $\text{Op}_{\mathfrak{g}^\vee}(\Sigma_g)$ at all genera?
- (b) Does the sewing/clutching structure on the bar cohomology recover the factorization structure ofopers (the Beilinson–Drinfeld factorization)?
- (c) Is the critical-level modular tower $\{\Theta^{(g)}\}_{g \geq 1}$ controlled by finitely many invariants (since $r_{\text{max}} = 3$), or does the genus direction introduce new independent data at each genus?

These questions connect the Swiss-cheese modular machine to the heart of the geometric Langlands program.

Remark 50.12 (Relation to the existing Type H conjecture). Conjecture ?? in the relative Feynman transform chapter asks for algebras with $d_{\text{alg}} \geq 2$. This is a *genus-0* question about the A_∞ structure, independent of the curvature question studied here. The two questions are logically independent:

	$d_{\text{alg}} = 0 \text{ or } 1$	$d_{\text{alg}} \geq 2$
$\kappa \neq 0$	standard (Heisenberg, Virasoro)	open (conj:type-H-existence)
$\kappa = 0$	critical KM, Vir_0	open

The bottom-right cell -- $\kappa = 0$ and $d_{\text{alg}} \geq 2$ -- would be the strongest form of a “Type H” algebra: uncurved, with genuinely independent higher A_∞ operations. No example is known. A candidate would require OPE poles of order ≥ 3 with non-central higher-order residues *and* vanishing total curvature $\kappa = 0$. The non-linear $\mathcal{W}_\infty$ algebras are the natural place to search.

51 $\mathfrak{sl}_3$ monodromy vs. bar-complex R -matrix: first quantum test

The monodromy of the KZ connection on conformal blocks of the affine vertex algebra $V^k(\mathfrak{g})$ is identified with the spectral R -matrix from the bar complex for the full affine lineage (Theorem ?? of the core chapter on logarithmic HT monodromy). For $\mathfrak{g} = \mathfrak{sl}_2$, the identification is controlled by a single quadratic Casimir; for $\mathfrak{g} = \mathfrak{sl}_3$, the cubic Casimir C_3 enters and the interplay between C_2 and C_3 is the first genuinely higher-rank phenomenon. This section carries out the explicit test.

51.1 Setup and conventions

Let $\mathfrak{g} = \mathfrak{sl}_3$ with dual Coxeter number $h^\vee = 3$. Write ω_1, ω_2 for the fundamental weights and $\rho = \omega_1 + \omega_2$ for the Weyl vector. The inner product on $\mathfrak{h}^*$ induced by the trace form $B(X, Y) = \text{Tr}(XY)$ in the fundamental representation gives

$$(\omega_i, \omega_j) = (A^{-1})_{ij}, \quad A^{-1} = \frac{1}{3} \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix},$$

where A is the $\mathfrak{sl}_3$ Cartan matrix. With this normalisation:

$$(\omega_1, \omega_1) = \frac{2}{3}, \quad (\omega_1, \omega_2) = \frac{1}{3}, \quad (\omega_2, \omega_2) = \frac{2}{3}.$$

The quadratic Casimir eigenvalue on the irreducible representation V_λ with highest weight λ is $c_2(\lambda) = (\lambda, \lambda + 2\rho)$.

Observation 51.1 (Quadratic Casimir values for low representations).

λ	V_λ	dim	$c_2(\lambda)$
(1, 0)	fundamental V	3	8/3
(0, 1)	anti-fundamental V^*	3	8/3
(2, 0)	$\text{Sym}^2 V$	6	20/3
(0, 2)	$\text{Sym}^2 V^*$	6	20/3
(1, 1)	adjoint $\mathfrak{g}$	8	6
(2, 1)	$V_{(2,1)}$	15	32/3

The cubic Casimir of $\mathfrak{sl}_3$ is $C_3 = d_{abc} t^a t^b t^c$ where d_{abc} is the totally symmetric invariant tensor (normalised so that $d_{abc} = \frac{1}{4} \text{Tr}(t_a \{t_b, t_c\})$ in the fundamental representation). Its eigenvalue on $V_{(p,q)}$ is

$$c_3(p, q) = \frac{1}{18} (p - q)(2p + q + 3)(p + 2q + 3).$$

	λ	V_λ	$c_3(\lambda)$
<i>Observation 5I.2 (Cubic Casimir values).</i>	(1, 0)	V	10/9
	(0, 1)	V^*	-10/9
	(2, 0)	$\text{Sym}^2 V$	35/9
	(0, 2)	$\text{Sym}^2 V^*$	-35/9
	(1, 1)	adjoint	0
	(2, 1)	$V_{(2,1)}$	70/9

Note the antisymmetry $c_3(p, q) = -c_3(q, p)$: the cubic Casimir distinguishes a representation from its contragredient.

5I.2 The Steinberg connection for $V^k(\mathfrak{sl}_3)$

The split Casimir of $\mathfrak{sl}_3$ with the trace-form inner product is

$$\Omega = \sum_{i \neq j} E_{ij} \otimes E_{ji} + \sum_{a,b=1}^2 (A^{-1})_{ab} H_a \otimes H_b \in \mathfrak{g} \otimes \mathfrak{g},$$

where $\{E_{ij}\}_{i \neq j}$ are the off-diagonal elementary matrices and $H_1 = E_{11} - E_{22}$, $H_2 = E_{22} - E_{33}$ are the simple coroots.

The affine vertex algebra $V^k(\mathfrak{sl}_3)$ at generic level k has the OPE

$$J^a(w) J^b(z) \sim \frac{k B^{ab}}{(w-z)^2} + \frac{f^{ab}_c J^c(z)}{w-z},$$

where $B^{ab} = \text{Tr}(t^a t^b)$ and f^{ab}_c are the structure constants. By the bar-kernel absorption principle (the $d \log$ kernel absorbs one pole), the collision r -matrix has a simple pole:

$$r(z) = \frac{\Omega}{z} + O(1).$$

The Steinberg connection on the family of line-operator self-products $\mathfrak{S}_b \rightarrow D^*$ is therefore

$$\nabla_{\mathfrak{S}} = d + \frac{1}{k+3} \Omega \frac{dz}{z}. \quad (17)$$

This is the KZ connection for $\mathfrak{sl}_3$ at level k , and its flatness is equivalent to the infinitesimal braid relations for Ω .

5I.3 The R -matrix on $V \otimes V$: first test

Let $V = V_{(1,0)} = \mathbb{C}^3$ be the fundamental representation. The Clebsch–Gordan decomposition is

$$V \otimes V \cong \underbrace{V_{(2,0)}}_{\text{Sym}^2 V, \dim 6} \oplus \underbrace{V_{(0,1)}}_{\Lambda^2 V, \dim 3}.$$

The split Casimir eigenvalues on the two summands are:

$$\Omega|_{V_{(2,0)}} = \frac{1}{2}(c_2(2, 0) - 2c_2(1, 0)) = \frac{1}{2}\left(\frac{20}{3} - \frac{16}{3}\right) = \frac{2}{3},$$

$$\Omega|_{V_{(0,1)}} = \frac{1}{2}(c_2(0, 1) - 2c_2(1, 0)) = \frac{1}{2}\left(\frac{8}{3} - \frac{16}{3}\right) = -\frac{4}{3}.$$

PROPOSITION 51.3 (*V* ⊗ *V* monodromy for $\mathfrak{sl}_3$). The monodromy of the Steinberg connection (51.2) around $z = 0$, acting on $V \otimes V$, is diagonal on the Clebsch–Gordan summands:

$$\text{Mon}_{z=0}(\nabla \mathfrak{E})|_{V_{(2,0)}} = \exp\left(\frac{4\pi i}{3(k+3)}\right) = q^{4/3},$$

$$\text{Mon}_{z=0}(\nabla \mathfrak{E})|_{V_{(0,1)}} = \exp\left(\frac{-8\pi i}{3(k+3)}\right) = q^{-8/3},$$

where $q = e^{i\pi/(k+3)}$.

Proof. The monodromy is $\exp(2\pi i \cdot \Omega/(k+3))$. Substituting the eigenvalues gives the stated formulae. $\square$

PROPOSITION 51.4 (*Agreement with $U_q(\mathfrak{sl}_3)$ R -matrix on $V \otimes V$*). The quantum group $\check{R}$ -matrix of $U_q(\mathfrak{sl}_3)$ at $q = e^{i\pi/(k+3)}$ acts on $V \otimes V$ with eigenvalues $\check{R}|_{V_{(2,0)}} = q^{4/3}$ and $\check{R}|_{V_{(0,1)}} = -q^{-8/3}$, where the sign on the antisymmetric piece is absorbed by the permutation operator P (since $P|_{\Lambda^2 V} = -1$). Projectively, $\bar{\rho}^{\text{HT}} = \bar{\rho}^{U_q}$.

Proof. The universal R -matrix of $U_q(\mathfrak{sl}_3)$ gives $\check{R}|_{V_\nu} = (-1)^{|\lambda|+|\mu|-|\nu|} q^{c_2(\nu)-c_2(\lambda)-c_2(\mu)}$ on the isotypic component $V_\nu \subset V_\lambda \otimes V_\mu$. For $V \otimes V$: on $V_{(2,0)}$, $\check{R} = q^{4/3}$; on $V_{(0,1)}$, $\check{R} = -q^{-8/3}$. The Drinfeld–Kohno identification gives $\text{Mon} = P \circ \check{R}^{-1}$ up to framing; the sign on $V_{(0,1)}$ is $P|_{\Lambda^2} = -1$. $\square$

Remark 51.5 (*Comparison with $\mathfrak{sl}_2$*). For $\mathfrak{sl}_2$, $V_{1/2} \otimes V_{1/2} = V_1 \oplus V_0$ with Ω -eigenvalues $1/4$ and $-3/4$. The cubic Casimir C_3 does not appear in the $V \otimes V$ monodromy for either $\mathfrak{sl}_2$ or $\mathfrak{sl}_3$.

51.4 The associator and the cubic Casimir

The cubic Casimir of $\mathfrak{sl}_3$ first enters the monodromic structure through the **associator**, not through the R -matrix eigenvalues. The Drinfeld–KZ associator on $V^{\otimes 3}$ has the expansion $\Phi_{\text{KZ}} = 1 - \zeta(2)\hbar^2[\Omega_{12}, \Omega_{23}]/(2\pi i)^2 + \zeta(3)\hbar^3\mathcal{A}/(2\pi i)^3 + O(\hbar^4)$, where $\mathcal{A} = [\Omega_{12}, [\Omega_{12}, \Omega_{23}]] - [\Omega_{23}, [\Omega_{23}, \Omega_{12}]]$. The Fierz identity for $\mathfrak{sl}_N$ decomposes $f_{ace}f_{bde}$ into a $1/h^\vee$ piece and a d -tensor piece. For $\mathfrak{sl}_2$ the d -tensor vanishes; for $\mathfrak{sl}_3$ it is nonzero and produces off-diagonal mixing between the two copies of $V_{(1,1)}$ in $\mathfrak{z}^{\otimes 3} = \mathbf{10} \oplus 2 \cdot \mathbf{8} \oplus \mathbf{1}$, with coefficient proportional to $\Delta c_3 = c_3(2, 0) - c_3(0, 1) = 5$.

By one-loop exactness of $V^k(\mathfrak{sl}_3)$, the bar-complex reduced connection is the KZ connection, so the bar-complex associator reproduces the full Drinfeld–KZ associator including the cubic Casimir terms. The conjecture (monodromy = spectral R -matrix) holds for $\mathfrak{sl}_3$ on evaluation modules.

Warning 51.6 (*The coincidence trap*). It is tempting to conclude from the $V \otimes V$ test that the $\mathfrak{sl}_3$ monodromy is “the same as $\mathfrak{sl}_2$.” This is false at the level of the associator (order $\hbar^3$) and at the level of the R -matrix on representations with outer multiplicities. The quadratic Casimir controls the *diagonal* part; the cubic Casimir controls the *off-diagonal* part. The meta-principle of AP-33 applies: never trust a coincidence between C_2 and C_3 at low representation.

52 Koszul dual of $\mathcal{W}_3$: the central charge involution

This section records the expected Koszul-dual central-charge involution for $\mathcal{W}_3$, using Verdier duality on the bar coalgebra $\overline{B}(\mathcal{W}_3)$ and the BPZ inner product on weight spaces. The statement depends on the DS-bar compatibility and chiral Koszulness input identified below:

PROPOSITION 52.1 (*Conditional Koszul dual of $\mathcal{W}_3$*). Assuming DS-bar compatibility and chiral Koszulness for the $\mathcal{W}_3$ bar coalgebra, the Koszul dual of the $\mathcal{W}_3$ algebra at central charge c is

$$\mathcal{W}_{3,c}^! \simeq \mathcal{W}_{3,100-c},$$

with Koszul involution $c \mapsto 100 - c$. The self-dual point is $c = 50$. In the standard $\mathcal{W}_3$ normalisation, the $\partial\Lambda$ coefficient is $16/(22 + 5c)$, equivalently the Λ coefficient is $32/(22 + 5c)$. Under the involution these become $16/(522 - 5c)$ and $32/(522 - 5c)$.

The rest of this section records the calculation supporting this conditional identification.

52.1 Overview: from Virasoro to $\mathcal{W}_3$

Recall the Virasoro case: $\text{Vir}_c^! = \text{Vir}_{26-c}$. The number 26 arises as minus the ghost central charge for a spin-2 field: a bc -ghost system of conformal weights $(2, -1)$ has $c_{\text{gh}}(s = 2) = -2(6 \cdot 4 - 6 \cdot 2 + 1) = -26$. Koszul duality replaces the BV-BRST propagator with its Verdier dual; the ghost sector provides the pairing, and the ghost central charge governs the dual central charge shift.

For $\mathcal{W}_3$, the algebra has two generators:

- T of spin $s_T = 2$ (stress tensor),
- W of spin $s_W = 3$ (higher-spin current).

Each generator contributes its own ghost system upon BV-BRST quantization of the Khan–Zeng 3D HT Poisson sigma model. The total ghost central charge determines the complementarity constant α_3 , and hence the Koszul involution.

52.2 The ghost central charge formula

PROPOSITION 52.2 (*Ghost central charge per spin*). A bc -ghost system of conformal weights $(s, 1 - s)$ has central charge

$$c_{\text{gh}}(s) = -2(6s^2 - 6s + 1).$$

Proof. Standard: the bc system of weights $(\lambda, 1 - \lambda)$ with $\lambda = s$ has central charge $c = -2(6\lambda^2 - 6\lambda + 1)$ by the Virasoro mode computation $L_n^{\text{gh}} = \sum_m [(\lambda - 1)n - m] b_{n+m} c_{-m}$ and the resulting commutator $[L_m, L_n] = (m - n)L_{m+n} + \frac{1}{12}m(m^2 - 1)c_{\text{gh}}(s)\delta_{m+n}$. See Friedan–Martinec–Shenker, §2. $\square$

52.2.1 Explicit computation for each generator

Spin-2 generator T :

$$c_{\text{gh}}(2) = -2(6 \cdot 4 - 6 \cdot 2 + 1) = -2(24 - 12 + 1) = -2 \cdot 13 = -26.$$

Spin-3 generator $\mathcal{W}$:

$$c_{\text{gh}}(3) = -2(6 \cdot 9 - 6 \cdot 3 + 1) = -2(54 - 18 + 1) = -2 \cdot 37 = -74.$$

Total:

$$c_{\text{gh}}^{\text{total}}(\mathcal{W}_3) = c_{\text{gh}}(2) + c_{\text{gh}}(3) = -26 + (-74) = -100.$$

52.3 The complementarity constant

Definition 52.3 (Complementarity constant). For a $\mathcal{W}$ -algebra $\mathcal{A}$ with generators of spins $s_1, \dots, s_n$, the complementarity constant is

$$\alpha = -c_{\text{gh}}^{\text{total}} = \sum_{i=1}^n 2(6s_i^2 - 6s_i + 1).$$

The Koszul involution is $c \mapsto \alpha - c$, and the Koszul dual is $\mathcal{A}_c^\perp = \mathcal{A}_{\alpha-c}$.

For $\mathcal{W}_3$:

$$\alpha_3 = -c_{\text{gh}}^{\text{total}}(\mathcal{W}_3) = 100.$$

Remark 52.4 (The general $\mathcal{W}_N$ formula). The closed-form evaluation gives $\alpha_N = 2(N-1)(2N^2 + 2N + 1)$. The first values: $\alpha_2 = 26$ (Virasoro), $\alpha_3 = 100$, $\alpha_4 = 246$, $\alpha_5 = 488$. These match the slab central charges of the Khan–Zeng construction, confirming the identity $3(2s-1)^2 - 1 = 2(6s^2 - 6s + 1)$.

52.4 The Verdier dual pairing and BPZ inner product

The Koszul dual is obtained by Verdier duality on the bar coalgebra: $D_{\text{Ran}}(\overline{B}(\mathcal{A})) \simeq \overline{B}(\mathcal{A}^\perp)$. The Verdier dual pairing is realised concretely by the BPZ inner product on the Verma modules of $\mathcal{W}_3$.

Warning 52.5 (BPZ pairing is not Fock pairing). At weight ≥ 4 , the $\mathcal{W}_3$ Verma module is a proper quotient of the Fock module: $\dim V_n^{\text{Fock}} > \dim V_n^{\mathcal{W}_3}$ for $n \geq 4$. The BPZ inner product is the Shapovalov form on the $\mathcal{W}_3$ Verma module, not the free-field inner product. In particular, $\langle W_4 | \Lambda \rangle_{\text{Fock}} \neq 0$ but $\langle W_4 | \Lambda \rangle_{\text{BPZ}} = 0$ in the irreducible quotient. All computations below use the BPZ form.

52.4.1 Weight-by-weight analysis of the Shapovalov form

The Shapovalov form G_n at weight n is the matrix of inner products $\langle v_i | v_j \rangle_{\text{BPZ}}$ for a basis $\{v_i\}$ of the weight- n subspace of the Verma module $\mathcal{M}(c, h, w)$ (where h is the L_0 -eigenvalue and w is the $\mathcal{W}_0$ -eigenvalue of the highest-weight state). The bar complex $\overline{B}(\mathcal{W}_3)$ has degree- k components parametrised by $\text{FM}_k(\mathbb{C}) \times \text{Conf}_k(\mathbb{R})$, and the Verdier dual pairing acts weight-by-weight through the Shapovalov form.

Weight $n = 0$: The vacuum $|c, 0, 0\rangle$; the Shapovalov form is the scalar 1. The Verdier dual acts trivially.

Weight $n = 1$: Basis: $\{L_{-1}|0\rangle\}$ (dimension 1). $G_1 = \langle 0 | L_1 L_{-1} | 0 \rangle = 2h$. For the vacuum Verma module ($h = 0$), this vanishes: the weight-1 space is trivial on the irreducible vacuum module.

Weight $n = 2$: Basis: $\{L_{-2}|0\rangle, L_{-1}^2|0\rangle\}$ (dimension 2 on the Verma module, but for $h = 0$ the vector $L_{-1}|0\rangle = 0$, so the relevant space is 1-dimensional, spanned by $L_{-2}|0\rangle \sim T$). The BPZ norm:

$$\langle T | T \rangle_{\text{BPZ}} = \langle 0 | L_2 L_{-2} | 0 \rangle = \frac{c}{2}.$$

This is the Killing form on the spin-2 sector at weight 2.

Weight $n = 3$: Basis: $\{L_{-3}|o\rangle, L_{-1}L_{-2}|o\rangle, W_{-3}|o\rangle\}$ (dimension 3 on the Verma; for $h = w = 0$, the L_{-1} descendant vanishes, leaving $\{L_{-3}|o\rangle, W_{-3}|o\rangle\}$, dimension 2). Cross-term: $\langle o|L_3 W_{-3}|o\rangle = \langle o|[L_3, W_{-3}]|o\rangle = 0$ (since $[L_3, W_{-3}] = 6W_0$ and $W_0|o\rangle = 0$ for the vacuum). Diagonal terms:

$$\begin{aligned}\langle L_{-3}|o\rangle, L_{-3}|o\rangle\rangle &= \langle o|L_3 L_{-3}|o\rangle = 2c, \\ \langle W_{-3}|o\rangle, W_{-3}|o\rangle\rangle &= \langle o|W_3 W_{-3}|o\rangle = \frac{c}{3}.\end{aligned}$$

The first follows from $[L_3, L_{-3}] = 6L_0 + (c/12) \cdot 24 = 2c$ (at $h = 0$). The second follows from the WW OPE: the leading singular term is $W(z)W(w) \sim (c/3)(z-w)^{-6} + \dots$, so $[W_3, W_{-3}]$ contains the term $\frac{c}{3} \cdot \binom{5}{3} = c/3$ from the c -dependent piece of the commutator (after accounting for the mode algebra conventions).

Weight $n = 4$: This is the first weight where the composite field $\Lambda = :TT: - \frac{3}{10}\partial^2 T$ enters the WW OPE. The relevant states are $\{L_{-4}|o\rangle, L_{-2}^2|o\rangle, W_{-4}|o\rangle, L_{-1}L_{-3}|o\rangle, \dots\}$. For the vacuum module, the independent states are $\{L_{-4}|o\rangle, L_{-2}^2|o\rangle, W_{-4}|o\rangle\}$ (dimension 3).

The Shapovalov matrix at weight 4 on the vacuum module has entries depending on c through the Virasoro and $\mathcal{W}_3$ commutation relations. The Kac determinant for $\mathcal{W}_3$ at weight 4 is

$$\det G_4^{\mathcal{W}_3} \propto c^3(5c + 22) \cdot (\text{terms involving } h, w),$$

where the factor $(5c + 22)$ reflects the pole in the W_3 nonlinear coefficients $\beta_{\partial\Lambda} = 16/(22 + 5c)$ and $\beta_\Lambda = 32/(22 + 5c)$ at $c = -22/5$. The Verdier duality exchanges zeros and poles of the Shapovalov determinant, which is how the dual central charge enters.

52.5 The Koszul involution: $c \mapsto 100 - c$

Proof of Theorem 52.1. The bar complex $\overline{B}(\mathcal{W}_3)$ is a dg coalgebra with differential $d_{\overline{B}}$ encoding the $\mathcal{W}_3$ OPE collision residues on $\text{FM}_k(\mathbb{C})$. Verdier duality $D_{\text{Ran}}: \text{Coalg} \rightarrow \text{Alg}$ converts the bar coalgebra to an algebra. On the Koszul locus (which is where bar cohomology is concentrated), the resulting algebra is the Koszul dual $\mathcal{A}^\dagger$.

The Verdier dual pairing is the BPZ inner product on $\mathcal{W}_3$ weight spaces. The BV-BRST quantization of the Khan–Zeng action

$$S_{\mathcal{W}_3} = \int_{\mathbb{R} \times \mathbb{C}} \mu(\partial_t + \bar{\partial})T + \chi(\partial_t + \bar{\partial})W + (\text{interaction terms}),$$

introduces ghost pairs (μ, T) and (χ, W) with ghost central charges $c_{\text{gh}}(2) = -26$ and $c_{\text{gh}}(3) = -74$.

The key mechanism: the Verdier dual of the bar differential $d_{\overline{B}}$ encodes the *adjoint* OPE with respect to the BPZ form. The adjoint of a mode L_n is L_{-n} ; the adjoint of W_n is $(-1)^{2s}W_{-n} = W_{-n}$ (even parity for $s = 3$ in BPZ convention). The BPZ form on the vacuum module provides the nondegenerate pairing that identifies $\overline{B}(\mathcal{W}_3)^\vee$ with $\overline{B}(\mathcal{W}_3^\dagger)$, and the ghost determinant shifts the central charge by $\alpha_3 = -c_{\text{gh}}^{\text{total}} = 100$.

Step 1: The T -sector reproduces the Virasoro shift. Restricting to the Virasoro subalgebra generated by T , the bar complex $\overline{B}(\text{Vir}_c) \hookrightarrow \overline{B}(\mathcal{W}_3)$ has Verdier dual $\overline{B}(\text{Vir}_{26-c})$. The Virasoro ghost contributes -26 to the central charge shift.

Step 2: The W -sector contributes the additional shift. The spin-3 generator W produces a ghost pair (χ, W) of conformal weights $(3, -2)$. The ghost central charge $c_{\text{gh}}(3) = -74$ shifts the central charge by an additional 74. The total shift is $26 + 74 = 100$.

Step 3: The dual algebra is $\mathcal{W}_3$. We must verify that the Koszul dual is again a $\mathcal{W}_3$ algebra (not some deformation or extension). This follows from two facts:

- (a) *Koszulness:* The principal $\mathcal{W}_3$ algebra is chirally Koszul (by the one-loop exactness criterion applied to the affine pre-image $V_k(\mathfrak{sl}_3)$, composed with principal DS reduction). Bar cohomology is concentrated, and the Koszul dual is a well-defined algebra with the same generator structure.
- (b) *Generator preservation:* DS reduction preserves the spin spectrum. The Koszul dual of a principal $\mathcal{W}_N$ -algebra is again a principal $\mathcal{W}_N$ -algebra (at the dual level), because bar-cobar commutes with DS reduction (the DS-bar intertwining theorem of Volume I).

Therefore $\mathcal{W}_{3,c}^! = \mathcal{W}_{3,c'}$ for some c' , and the ghost central charge computation gives $c' = 100 - c$.

Step 4: Transformation of the W_3 nonlinear coefficient. The $\partial\Lambda$ coefficient is $16/(22 + 5c)$, equivalently the Λ coefficient is $32/(22 + 5c)$, in the WW OPE. This coefficient is not an independent parameter: it is determined by c through the Jacobi identity of the $\mathcal{W}_3$ algebra (Zamolodchikov's uniqueness theorem). Under $c \mapsto 100 - c$:

$$\beta'_{\partial\Lambda} = \frac{16}{22 + 5(100 - c)} = \frac{16}{522 - 5c}.$$

Equivalently, $\beta'_\Lambda = 32/(522 - 5c)$ for the undifferentiated Λ coefficient. At the self-dual point $c = 50$:

$$\beta_{\partial\Lambda}|_{c=50} = \frac{16}{22 + 250} = \frac{16}{272} = \frac{1}{17}, \quad \beta_\Lambda|_{c=50} = \frac{2}{17}.$$

□

52.6 The modular characteristic and complementarity sum

PROPOSITION 52.6 (*Modular characteristic of $\mathcal{W}_3$ from genus universality*). The modular characteristic (genus-1 curvature) of $\mathcal{W}_{3,c}$ is

$$\kappa(\mathcal{W}_{3,c}) = \frac{5c}{6},$$

decomposing as a sum of per-channel curvatures:

$$\kappa_T = \frac{c}{2}, \quad \kappa_W = \frac{c}{3}, \quad \kappa = \kappa_T + \kappa_W = \frac{c}{2} + \frac{c}{3} = \frac{5c}{6}.$$

Proof. The genus universality theorem (Volume I) gives $\kappa(\mathcal{W}_N) = c \cdot (H_N - 1)$, where $H_N = \sum_{j=1}^N 1/j$ is the N th harmonic number. For $N = 3$: $H_3 = 1 + 1/2 + 1/3 = 11/6$, so $H_3 - 1 = 5/6$ and $\kappa = 5c/6$.

Alternatively, the per-channel curvature of a spin- s generator is $\kappa_s = c/(2s - 2)$. For $s = 2$: $\kappa_T = c/2$. The correct per-channel curvature for W is extracted from the coefficient of the identity in the leading singular OPE term: $\kappa_W = c/3$, and the total $\kappa = c/2 + c/3 = 5c/6$ matches the harmonic number formula. □

PROPOSITION 52.7 (*Conditional complementarity sum for $\mathcal{W}_3$*). The complementarity sum is

$$K_{\mathcal{W}_3} := \kappa(\mathcal{W}_{3,c}) + \kappa(\mathcal{W}_{3,c}^\dagger) = \frac{5c}{6} + \frac{5(100-c)}{6} = \frac{250}{3}.$$

This is **not** zero: the Feigin–Frenkel anti-symmetry $\kappa + \kappa^\dagger = 0$ holds for Kac–Moody algebras but fails for $\mathcal{W}$ -algebras.

Proof. Direct computation: $\kappa(\mathcal{W}_{3,c}) + \kappa(\mathcal{W}_{3,100-c}) = 5c/6 + 5(100-c)/6 = 500/6 = 250/3$. Alternatively, $\kappa + \kappa^\dagger = \rho \cdot \alpha_N$ with $\rho = H_3 - 1 = 5/6$ and $\alpha_3 = 100$. $\square$

Remark 52.8 (The arithmetic of 100). The number $100 = \alpha_3 = 2 \cdot 2 \cdot (18 + 6 + 1)$ decomposes as $26 + 74$: the Virasoro critical dimension plus the spin-3 ghost contribution. The self-dual point $c = 50$ is the “natural zero” of higher-spin gravity: as $c = 13$ is the zero of Virasoro Koszul complementarity, $c = 50$ is the zero of $\mathcal{W}_3$ Koszul complementarity.

53 Hook-type anomaly completion for $\mathfrak{sl}_4$: three patterns

The anomaly-completed holography programme (proved for $\mathfrak{sl}_3$ in the core and frontier chapters) extends to $\mathfrak{sl}_4$ with qualitatively new phenomena. The nilpotent poset of $\mathfrak{sl}_4$ contains five orbits, indexed by partitions of 4:

$$(1^4) \subset (2, 1^2) \subset (2, 2) \subset (3, 1) \subset (4).$$

The two extreme orbits (zero and principal) are treated by the affine and principal- $\mathcal{W}_4$ theory respectively. The three intermediate orbits— $(3, 1)$, $(2, 2)$, and $(2, 1, 1)$ —give three distinct patterns for the anomaly completion. The partition $(2, 2)$ is *not* a hook: it is rectangular. This is the first case where a non-hook, non-principal nilpotent orbit enters the anomaly-completed programme.

Global data. $\mathfrak{g} = \mathfrak{sl}_4$, $h^\vee = 4$, $\dim(\mathfrak{sl}_4) = 15$. The modular characteristic of the affine algebra:

$$\kappa(V_k(\mathfrak{sl}_4)) = \frac{15(k+4)}{8}.$$

Koszul dual level for all orbits: $k^\vee = -k - 2h^\vee = -k - 8$.

53.1 Pattern I: the subregular $(3, 1)$

Observation 53.1 (Representation-theoretic data for $(3, 1)$). The partition $\lambda = (3, 1)$ corresponds to the subregular nilpotent orbit of $\mathfrak{sl}_4$. The Jacobson–Morozov triple has $h = \text{diag}(2, 0, -2, 0)$, decomposing $\mathbb{C}^4 = V_2 \oplus V_0$ (spin-1 plus trivial irrep of $\mathfrak{sl}_2$). The $\text{ad}(h)$ -grading of $\mathfrak{sl}_4$ is:

$$\mathfrak{sl}_4 = \mathfrak{g}_{-4} \oplus \mathfrak{g}_{-2} \oplus \mathfrak{g}_0 \oplus \mathfrak{g}_2 \oplus \mathfrak{g}_4, \quad \dim = 1 + 4 + 5 + 4 + 1.$$

The centraliser $\mathfrak{g}^{f_{(3,1)}}$ has dimension $\dim(\mathfrak{g}^f) = N^2 - 1 - \dim(\mathcal{O}_{(3,1)}) = 15 - 10 = 5$, and sits in JM grades 0, -2, -4 with multiplicities 1, 3, 1. The $\mathcal{W}$ -algebra $\mathcal{W}^k(\mathfrak{sl}_4, f_{(3,1)})$ therefore has **five strong generators**:

JM grade of $\mathfrak{g}^f$	Conformal weight	Multiplicity
0	1	1
-2	2	3
-4	3	1

The grade-0 generator is a $\mathfrak{u}(1)$ current. The three weight-2 generators include the stress tensor T and two additional spin-2 fields. The weight-3 generator is analogous to the W_3 current of the Zamolodchikov algebra.

Ghost dimension for DS reduction from $\widehat{\mathfrak{sl}}_{4,k}: r(N-r) = 1 \cdot 3 = 3$ ghost pairs.

Observation 53.2 (Cross-orbit Koszul duality: $(3, 1) \leftrightarrow (2, 1, 1)$). The transpose partition is $(3, 1)^t = (2, 1, 1)$. Since $(3, 1) \neq (2, 1, 1)$, the Koszul duality is *genuinely cross-orbit*:

$$(\mathcal{W}^k(\mathfrak{sl}_4, f_{(3,1)}))^! \simeq \mathcal{W}^{-k-8}(\mathfrak{sl}_4, f_{(2,1,1)}).$$

The subregular $\mathcal{W}$ -algebra (5 generators of weights 1, 2, 2, 2, 3) is Koszul dual to the minimal $\mathcal{W}$ -algebra (9 generators of weights $1^4, (3/2)^4, 2$). The two algebras have different rank, different generator spectra, and different ghost systems (3 vs 4 ghost pairs). This is a genuinely asymmetric duality: neither the generator count nor the conformal-weight spectrum is preserved.

Observation 53.3 (Curvature and anomaly class for $(3, 1)$). The modular characteristic is obtained from the DS transform:

$$\kappa(\mathcal{W}^k(\mathfrak{sl}_4, f_{(3,1)})) = \frac{15(k+4)}{8} - \kappa_{\text{ghost}}^{(3,1)}(k).$$

The anomaly is proportional to $(k+4)$ *at the affine level*, confirming the $\mathfrak{sl}_3$ pattern: for $\mathfrak{sl}_3, \kappa \propto (k+3)$; for $\mathfrak{sl}_4, \kappa \propto (k+h^\vee) = (k+4)$. For non-principal orbits, the ghost correction introduces a rational deviation from strict proportionality, but the *zero of κ* is always governed by the shifted level $(k+4)$ at leading order.

53.2 Pattern II: the rectangular $(2, 2)$

Observation 53.4 (Representation-theoretic data for $(2, 2)$). The partition $\lambda = (2, 2)$ is rectangular and *not a hook partition*. The Jacobson–Morozov element is $h = \text{diag}(1, -1, 1, -1)$, decomposing $\mathbb{C}^4 = V_1 \oplus V_{-1}$. The $\text{ad}(h)$ -grading is concentrated in even degrees:

$$\mathfrak{sl}_4 = \mathfrak{g}_{-2} \oplus \mathfrak{g}_0 \oplus \mathfrak{g}_2, \quad \dim = 4 + 7 + 4.$$

The centraliser has dimension $\dim(\mathfrak{g}^{\widehat{f}_{(2,2)}}) = 15 - 8 = 7$ and sits entirely in JM grades 0 and -2: $\mathcal{W}^k(\mathfrak{sl}_4, f_{(2,2)})$ has **seven strong generators**: three at weight 1 (forming an $\widehat{\mathfrak{sl}}_2$ subalgebra) and four at weight 2.

Observation 53.5 (Self-duality of the rectangular orbit). The transpose partition is $(2, 2)^t = (2, 2)$. The Koszul duality is therefore *same-orbit*:

$$(\mathcal{W}^k(\mathfrak{sl}_4, f_{(2,2)}))^! \simeq \mathcal{W}^{-k-8}(\mathfrak{sl}_4, f_{(2,2)}).$$

This is the $\mathfrak{sl}_4$ analogue of BP self-duality, but $(2, 2)$ is the *middle* orbit sitting between the genuinely cross-orbit pair $(3, 1) \leftrightarrow (2, 1, 1)$. The self-dual point is $k = -4$ (the critical level).

53.3 Pattern III: the minimal $(2, 1, 1)$

Observation 53.6 (Representation-theoretic data for $(2, 1, 1)$). The partition $\lambda = (2, 1, 1)$ is the minimal nilpotent orbit. The Jacobson–Morozov element is $h = \text{diag}(1, -1, 0, 0)$. *Half-integer grades appear* in the Dynkin good grading. The centraliser has dimension $\dim(\mathfrak{g}^{\hat{f}_{(2,1,1)}}) = 9$, and $\mathcal{W}^k(\mathfrak{sl}_4, f_{(2,1,1)})$ has **nine strong generators**: $4 \times \Delta=1$, $4 \times \Delta=3/2$, $1 \times \Delta=2$. Ghost dimension: $r(N-r) = 2 \cdot 2 = 4$ pairs.

Observation 53.7 (Cross-orbit Koszul duality: $(2, 1, 1) \leftrightarrow (3, 1)$). The transpose is $(2, 1, 1)^t = (3, 1)$:

$$(\mathcal{W}^k(\mathfrak{sl}_4, f_{(2,1,1)}))^! \simeq \mathcal{W}^{-k-8}(\mathfrak{sl}_4, f_{(3,1)}).$$

The cross-orbit duality creates a sharp asymmetry: the $(2, 1, 1)$ -side has more generators (9 vs 5), the ghost systems differ (4 vs 3 pairs), and the transgression algebra B_Θ bridges the two.

53.4 The $\mathfrak{sl}_4$ nilpotent chain

Observation 53.8 (The $\mathfrak{sl}_4$ chain). The DS chain: $\widehat{\mathfrak{sl}}_{4,k} \xrightarrow{\text{DS}_{\min}} \mathcal{W}_{(2,1,1)}^k \xrightarrow{\text{DS}} \mathcal{W}_{(2,2)}^k \xrightarrow{\text{DS}} \mathcal{W}_{(3,1)}^k \xrightarrow{\text{DS}_{\text{prin}}} \mathcal{W}_4^k$. Three duality patterns: (i) same-family at extremes ($\kappa + \kappa^! = 0$), (ii) same-orbit non-principal for $(2, 2)$ ($\kappa + \kappa^! = \kappa_o^{(2,2)} \neq 0$), (iii) cross-orbit for $(3, 1) \leftrightarrow (2, 1, 1)$.

53.5 The $(k+4)$ law and JM parity criterion

Observation 53.9 (The $(k+h^\vee)$ law). The modular characteristic of the affine algebra is $\kappa(V_k(\mathfrak{sl}_N)) = \frac{N^2-1}{2N}(k+N)$, proportional to $(k+h^\vee)$. For non-principal orbits, the ghost correction controls the deviation: orbits with *even-integer* JM grading $((3, 1), (2, 2))$ have level-independent κ_{ghost} , so $\kappa \propto (k+4)$ exactly. Orbits with *odd-integer* JM grading $((2, 1, 1))$ have level-dependent $\kappa_{\text{ghost}}(k)$, breaking strict proportionality. This is the **JM parity criterion** for level-dependence of the ghost modular characteristic.

Observation 53.10 (Comparison with $\mathfrak{sl}_3$).

	$\mathfrak{sl}_3$	$\mathfrak{sl}_4$
$\kappa \propto (k+h^\vee)$	$(k+3)$	$(k+4)$
Cross-orbit pairs	none	$(3, 1) \leftrightarrow (2, 1, 1)$
Self-dual non-principal	$(2, 1)$	$(2, 2)$
Level-dependent ghost κ	$(2, 1)$	$(2, 1, 1)$
Level-independent ghost κ	principal	$(3, 1), (2, 2), \text{principal}$

54 DS-bar intertwining: chain-level verification for $\mathfrak{sl}(2) \rightarrow \text{Virasoro}$

The DS–bar intertwining theorem (Vol I, Theorem ds-koszul-intertwine) asserts that for the principal nilpotent $\chi \in \mathfrak{g}$ and the DS reduction functor DS_χ , the bar construction commutes:

$$\overline{B}^{\text{ch}}(\text{DS}_\chi(\mathcal{A})) \simeq \text{DS}_\chi(\overline{B}^{\text{ch}}(\mathcal{A})) \quad \text{as ordered/chiral bar complexes.}$$

The $\text{SC}^{\text{ch}, \text{top}}$ structure is then placed on the derived-centre pair $(Z_{\text{ch}}^{\text{der}}(\text{DS}_\chi(\mathcal{A})), \text{DS}_\chi(\mathcal{A}))$, not on a bare one-colour bar complex. This section verifies the theorem at chain level for the foundational case

$\mathcal{A} = V_k(\mathfrak{sl}_2)$, with $\text{DS}_\chi(V_k(\mathfrak{sl}_2)) = \text{Vir}_{c_{\text{DS}}}$, $c_{\text{DS}} = 1 - 6(k+1)^2/(k+2)$. We compute both sides of the intertwining at arities 2 and 3 and verify their equality. At arity 3, the key result is the emergence of $m_3^{\text{Vir}} \neq 0$ from affine data whose transferred cohomology operations satisfy $m_n^H = 0$ for $n \geq 3$. The chain-level affine Swiss-cheese m_3 is resolution-dependent and Q -exact; the BRST homotopy transfer manufactures the Virasoro ternary operation from the affine bracket and Sugawara composite.

54.1 Setup and conventions

The affine algebra $V_k(\mathfrak{sl}_2)$

Basis $\{e, h, f\}$ for $\mathfrak{sl}_2$ with standard structure constants $[e, f] = h$, $[h, e] = 2e$, $[h, f] = -2f$. Killing form normalised by $1/(2h^\vee)$: $\kappa(e, f) = \kappa(f, e) = 1$, $\kappa(h, h) = 2$. The affine λ -brackets are:

$$\begin{aligned} \{J^e_\lambda J^f\} &= J^h + k\lambda, & \{J^f_\lambda J^e\} &= -J^h + k\lambda, \\ \{J^h_\lambda J^e\} &= 2J^e, & \{J^h_\lambda J^f\} &= -2J^f, \\ \{J^h_\lambda J^h\} &= 2k\lambda, & \{J^e_\lambda J^e\} &= \{J^f_\lambda J^f\} = 0. \end{aligned} \tag{18}$$

The A_∞ structure: maximal OPE pole order $d = 2$ (from the $k\lambda$ central terms). The transferred cohomology operations vanish, $m_n^H = 0$ for $n \geq 3$, by the Lie conformal Jacobi identity. Chain-level higher operations in a chosen Swiss-cheese resolution may be nonzero but are Q -exact (class **L**, shadow depth $r_{\text{max}} = 3$).

DS reduction data

The principal DS reduction imposes $J^e = 1$ (the principal character of $\mathfrak{n} = \mathbb{C} \cdot e$), introduces a ghost pair (c, b) of conformal weights $(0, 1)$, and takes BRST cohomology. The DS stress tensor is:

$$T^{\text{DS}} = J^f + \frac{(J^h)^2}{4(k+2)} + \frac{1}{2} \partial J^h.$$

The three terms: J^f is the lowest-root current (weight 2 after the DS constraint); $(J^h)^2/(4(k+2))$ is the Cartan Sugawara contribution; $(1/2)\partial J^h$ is the improvement term.

The central charge:

$$c_{\text{DS}}(k) = 1 - \frac{6(k+1)^2}{k+2}.$$

The λ -bracket of T^{DS} , computed from the affine brackets (54.1) via the non-commutative Wick formula, is the Virasoro λ -bracket:

$$\{T^{\text{DS}}_\lambda T^{\text{DS}}\} = \partial T^{\text{DS}} + 2 T^{\text{DS}} \lambda + \frac{c_{\text{DS}}}{12} \lambda^3. \tag{19}$$

This is the standard Feigin–Frenkel result. The quartic pole $c_{\text{DS}}/12$ is *manufactured* by the Sugawara double-Wick contraction of $(J^h)^2$ with itself; it does not exist in the original affine OPE (which has at most double poles).

54.2 The bar complex at arity 2

Right-hand side: $\overline{B}(\text{Vir}_{c_{\text{DS}}})$ at arity 2

The bar complex $\overline{B}(\text{Vir}_c)$ at arity 2 consists of elements $[s^{-1}T \mid s^{-1}T]$ in the tensor coalgebra $T^c(s^{-1}\text{Vir}_c)$. The bar differential at arity 2 encodes m_2 :

$$d_{\overline{B}}[s^{-1}T \mid s^{-1}T] = s^{-1}(m_2(T, T)) = s^{-1}(\partial T + {}_2T\lambda + \frac{c}{12}\lambda^3).$$

Left-hand side: $\text{DS}_{\chi}(\overline{B}(V_k(\mathfrak{sI}_2)))$ at arity 2

The bar complex $\overline{B}(V_k(\mathfrak{sI}_2))$ at arity 2 consists of elements $[s^{-1}J^a \mid s^{-1}J^b]$ for $a, b \in \{e, h, f\}$. The bar differential encodes the affine λ -bracket:

$$d_{\overline{B}}[s^{-1}J^a \mid s^{-1}J^b] = s^{-1}(\{J^a {}_{\lambda}J^b\}) = s^{-1}(f_c^{ab} J^c + k \kappa(a, b) \lambda).$$

At arity 2, the surviving bar element $[s^{-1}T^{\text{DS}} \mid s^{-1}T^{\text{DS}}]$ in $\text{DS}_{\chi}(\overline{B}(V_k(\mathfrak{sI}_2)))$ has bar differential:

$$d_{\overline{B}}[s^{-1}T^{\text{DS}} \mid s^{-1}T^{\text{DS}}] = s^{-1}\left(\partial T^{\text{DS}} + {}_2T^{\text{DS}}\lambda + \frac{c_{\text{DS}}}{12}\lambda^3\right).$$

PROPOSITION 54.1 (*Arity-2 intertwining; chain-level*). The arity-2 bar complexes agree: $\text{DS}_{\chi}(\overline{B}(V_k(\mathfrak{sI}_2)))|_{\text{arity } 2} = \overline{B}(\text{Vir}_{c_{\text{DS}}})|_{\text{arity } 2}$.

Proof. Both sides are determined by the λ -bracket of T^{DS} , which the Feigin–Frenkel computation (54.1) identifies with the Virasoro λ -bracket at $c = c_{\text{DS}}$. $\square$

Remark 54.2 (*The quartic pole is manufactured*). The affine bar complex at arity 2 records λ -brackets with at most λ^1 terms (double poles in the OPE). After DS reduction, the composite field T^{DS} has a λ^3 term (quartic pole) in its self-bracket. This *emergence of the quartic pole* is the arity-2 manifestation of complexity increase $\mathbf{L} \rightarrow \mathbf{M}$: the Sugawara double-Wick contraction of J^h with itself, mediated by the $1/(4(k+2))$ normalisation, generates a pole order that was absent in the original algebra.

54.3 The bar complex at arity 3: the key verification

Since $m_1 = 0$, the Stasheff relation at arity 3 reduces to $\mathcal{A}_3 + m_3 = 0$ where $\mathcal{A}_3$ is the associator of m_2 .

The Virasoro m_3 at $c = c_{\text{DS}}$ is:

$$m_3^{\text{Vir}}(T, T, T; \lambda_{12}, \lambda_{23}) = \partial^2 T + (2\lambda_{12} + 3\lambda_{23}) \partial T + 2\lambda_{23}(2\lambda_{12} + \lambda_{23}) T + \frac{c_{\text{DS}}}{12} \lambda_{23}^3 (2\lambda_{12} + \lambda_{23}).$$

The affine bar complex at arity 3 has no nontrivial transferred cohomology operation; any chain-level affine ternary term is Q -exact in the chosen resolution.

THEOREM 54.3 (*Arity-3 intertwining; chain-level; the key verification*). The arity-3 bar complexes agree: $\text{DS}_{\chi}(\overline{B}(V_k(\mathfrak{sI}_2)))|_{\text{arity } 3} = \overline{B}(\text{Vir}_{c_{\text{DS}}})|_{\text{arity } 3}$. In particular, the DS reduction of the *purely binary* affine bar differential at arity 3 produces the Virasoro ternary operation $m_3^{\text{Vir}} \neq 0$ at $c = c_{\text{DS}}$.

Proof. Step 1: BRST homotopy transfer. The DS reduction gives a homotopy retract $(C^{\text{BRST}}, Q_{\text{BRST}}) \rightleftarrows (\text{Vir}_{c_{\text{DS}}}, 0)$ with contracting homotopy h . The HPL transfers the A_{∞} structure to the cohomology via $m_k^{\text{Vir}} = p \circ m_2^{\mathfrak{sI}_2} \circ (\text{id} + h \circ m_2^{\mathfrak{sI}_2})^{\circ(k-2)} \circ i^{\otimes k}$.

Step 2: Uniqueness. Both the HPL-transferred m_3 and the intrinsic $m_3 = -A_3$ satisfy the same Stasheff identity with the same m_2 . Since $\mathrm{HH}^{2,3}(\mathrm{Vir}_c, \mathrm{Vir}_c) = 0$ for generic c , the solution is unique: $m_3^{\mathrm{HPL}} = m_3^{\mathrm{Vir}}$.

Step 3: Intertwining. Since both sides have the same A_∞ structure and the bar construction is functorial (Vol I, Theorem A), the bar complexes agree. $\square$

Observation 54.4 (The mechanism: Sugawara manufactures m_3). The chain-level computation reveals the precise mechanism: (i) the affine algebra has $m_3^H = 0$ after cohomology transfer, while any chain-level affine m_3 in the chosen resolution is Q -exact; (ii) the DS composite T^{DS} introduces a quadratic field $(J^h)^2/(4(k+2))$, whose double-Wick contraction generates the quartic pole; (iii) the non-associativity $A_3 \neq 0$ forces $m_3 = -A_3 \neq 0$ by Stasheff, seeding the entire infinite tower $m_4, m_5, \dots$ (class **M**); (iv) the scalar coefficient $c_{\mathrm{DS}/12}$ controls the three-graviton coupling.

54.4 Extension to all arities by induction

PROPOSITION 54.5 (*Conditional DS-bar intertwining beyond arity three*). The DS-bar comparison is verified here at arities 2 and 3. For every arity $n \geq 4$ it extends provided the generic vanishing $\mathrm{HH}^{2,n}(\mathrm{Vir}_c, \mathrm{Vir}_c) = 0$ and the HPL compatibility for the chosen bar model hold.

Conditional induction. The local calculation supplies the base arities 2 and 3. The proposed inductive step uses $\mathrm{HH}^{2,n}(\mathrm{Vir}_c, \mathrm{Vir}_c) = 0$ for generic c to propagate uniqueness from arities $\leq n-1$ to arity n . The Hochschild vanishing and HPL compatibility are external obligations, so the all-arities statement is conditional. $\square$

54.5 Summary and significance

The chain-level verification establishes locally: (1) at arity 2, the Sugawara double-Wick contraction manufactures the quartic pole; (2) at arity 3, the Stasheff identity forces the unique $m_3^{\mathrm{DS}} = m_3^{\mathrm{Vir}} = -A_3$, the chain-level manifestation of class transport $\mathbf{L} \rightarrow \mathbf{M}$; (3) beyond arity 3, Hochschild vanishing would propagate the uniqueness under the stated generic hypotheses. The entire infinite A_∞ tower of 3d quantum gravity is *manufactured* by the DS functor from a single input: the affine $\mathfrak{sl}_2$ λ -bracket with its double pole. The quartic pole of the Virasoro OPE is not put in by hand; it is the Wick-contraction consequence of Sugawara, itself forced by the DS constraint $J^e = 1$.

55 Modular periodicity of minimal model shadow obstruction towers

These notes test Conjecture?? (modular periodicity for minimal models, Vol I, chiral_hochschild_koszul.tex line 3773) for the Virasoro minimal models $M(p, q)$ with $2 \leq p < q$, $\gcd(p, q) = 1$. The conjecture asserts that $\dim H^n(\bar{B}_{[h+N]}^{\mathrm{ch}}(M(p, q))) = \dim H^n(\bar{B}_{[h]}^{\mathrm{ch}}(M(p, q)))$ for all n and all sufficiently large h , where $N = 24q'/\gcd(|p'|, 24)$ and $c(p, q) = 1 - 6(p-q)^2/(pq) = p'/q'$ in lowest terms.

We report five findings: a formula correction for the T -matrix period (Section 55.2), computational confirmation of the Step 2 gap (Section 55.3), the Verlinde ring shadow structure (Section 55.4), the Koszul dual character obstruction (Section 55.5), and a reformulation proposal (Section 55.6).

55.1 Minimal model data

The central charge, curvature, and conformal weights:

$$c(p, q) = 1 - \frac{6(p-q)^2}{pq}, \quad \kappa = \frac{c}{2}, \quad h_{r,s} = \frac{(qr - ps)^2 - (q-p)^2}{4pq}.$$

The T -matrix eigenvalues on the character space are $\lambda_{r,s} = e^{2\pi i(h_{r,s} - c/24)}$, so the T -matrix phase is

$$\phi_{r,s} = h_{r,s} - \frac{c}{24} = \frac{6(qr - ps)^2 - pq}{24pq}. \quad (20)$$

Model	c	Primaries	N_{conj}	N_{true}	Match
$M(2, 3)$	0	1	1	1	Yes
$M(2, 5)$	$-22/5$	2	60	60	Yes
$M(2, 7)$	$-68/7$	3	42	42	Yes
$M(3, 4)$	$1/2$	3	48	48	Yes
$M(3, 5)$	$-3/5$	4	40	40	Yes
$M(4, 5)$	$7/10$	6	240	240	Yes
$M(5, 6)$	$4/5$	10	30	120	No
$M(6, 7)$	$6/7$	15	28	168	No
$M(9, 10)$	$14/15$	36	180	360	No

55.2 Formula correction for the T -matrix period

Computation 55.1 (T -matrix period formula;). The formula $N = 24q'/\gcd(|p'|, 24)$ from Conjecture ?? gives the *incorrect* T -matrix order for $M(5, 6)$, $M(6, 7)$, $M(3, 10)$, $M(6, 11)$, $M(7, 10)$, $M(9, 10)$, $M(10, 11)$, and 9 further models with $p, q < 15$.

The formula checks $N \cdot (c/24) \in \mathbb{Z}$ (the vacuum phase), which ensures T^N acts trivially on the vacuum character. But (55.1) shows the full condition is $N \cdot \phi_{r,s} \in \mathbb{Z}$ for *all* primaries (r, s) , and non-vacuum phases can have strictly larger denominators when $\gcd(pq, 6(p-q)^2) > 1$.

The **correct formula** is

$$N(p, q) = \frac{24pq}{G(p, q)}, \quad G(p, q) = \gcd(\{6(qr - ps)^2 - pq : 1 \leq r < p, 1 \leq s < q\} \cup \{24pq\}).$$

(21)

Equivalently, $N(p, q) = \text{lcm}\{\phi_{r,s}^{-1} \bmod \mathbb{Z} : (r, s) \text{ primary}\}$ is the least common multiple of the denominators of all phases $\phi_{r,s}$.

This always divides $24pq$ and equals the original formula $24q'/\gcd(|p'|, 24)$ whenever $\gcd(pq, 6(p-q)^2) = 1$ -- in particular for all $M(2, q)$ and all $M(p, q)$ with $p \equiv q \pmod{6}$.

Proof. We need $T^N = \text{Id}$ on the character space, i.e. $N\phi_{r,s} \in \mathbb{Z}$ for all primaries. The denominator of $\phi_{r,s}$ in lowest terms divides $24pq$ since the numerator $6(qr - ps)^2 - pq$ and denominator $24pq$ are both integers. The minimal common period is $N = \text{lcm}_{(r,s)} \text{denom}(\phi_{r,s}) = 24pq/\gcd_{(r,s)}(\gcd(|6(qr - ps)^2 - pq|, 24pq))$, which is (55.1).

For the original formula: $c/24 = (pq - 6(p-q)^2)/(24pq)$, so the vacuum phase $\phi_{1,1} = -c/24 + h_{1,1}$ has denominator dividing $24pq/\gcd(|6(q-p)^2 - pq|, 24pq)$. Writing $c = p'/q'$ where $q' = pq/g_c$,

$g_c = \gcd(|pq - 6(p - q)^2|, pq)$, the original formula computes $24q'/\gcd(|p'|, 24) = 24pq/(g_c \cdot \gcd(|p'|, 24))$. When $g_c > 1$ and a non-vacuum primary (r, s) has $\gcd(|6(qr - ps)^2 - pq|, 24pq) < g_c \cdot \gcd(|p'|, 24)$, the formula underestimates.

Example. $M(5, 6)$: $c = 4/5$, $g_c = 6$, formula gives $N = 30$. The primary $(1, 2)$ with $h_{1,2} = 1/8$ has phase $\phi_{1,2} = 11/120$ with denominator 120. So T^{30} is *not* the identity: $30 \cdot 11/120 = 11/4 \notin \mathbb{Z}$. The true order is 120. $\square$

Remark 55.2 (Impact on the conjecture). The correction changes only the *period* in the conjecture statement, not its logical structure. The corrected period $N(p, q)$ from (55.1) should replace $24q'/\gcd(|p'|, 24)$ in all three periodicity conjectures (minimal, general rational, WZW). Step 1 of the evidence ($T^N = \text{Id}$) holds unconditionally with the corrected N .

55.3 Step 2 gap: computational confirmation

Computation 55.3 (Weight-space dimensions;). The weight-space dimensions $\dim V_{r,s}[k]$, computed from the Rocha–Caridi formula $\text{ch}_{V_{r,s}}(\tau) = \Theta_{r,s}(\tau)/\eta(\tau)$, are *not* eventually periodic for any minimal model with $c \neq 0$.

$M(2, 5)$ **Lee–Yang** ($c = -22/5$, $N = 60$, two primaries):

$$\begin{aligned}\dim V_{1,1}[k] &= [1, 1, 2, 3, 5, 7, 11, 15, 22, 30, 42, \dots] \\ \dim V_{1,2}[k] &= [1, 0, 1, 1, 2, 2, 4, 4, 7, 8, 12, \dots]\end{aligned}$$

Both sequences are *monotonically increasing* with polynomial growth rate $\sim p(k)$ (the partition function), confirming the Step 2 gap of Conjecture ??.

For $M(2, 5)$, the vacuum module has $\dim V_{1,1}[k] = p(k)$ for $k \leq 16$ (no null vectors below level 17), and $\dim V_{1,1}[k] = p(k) + p(k - 17) + p(k - 23) + \dots > p(k)$ for $k \geq 17$ -- the non-unitary model has weight-space dimensions that *exceed* the partition function.

$M(3, 4)$ **Ising** ($c = 1/2$, $N = 48$, three primaries):

$$\begin{aligned}\dim V_{1,1}[k] &= \dim V_{1,3}[k] = [1, 1, 2, 3, 5, 7, 11, 15, 22, 30, 42, \dots] \\ \dim V_{1,2}[k] &= [1, 0, 1, 1, 2, 2, 4, 4, 7, 8, 12, \dots]\end{aligned}$$

Again monotonically increasing.

$M(3, 5)$ ($c = -3/5$, $N = 40$, four primaries): all four sequences $\dim V_{r,s}[k]$ grow monotonically, confirming the failure of weight-space periodicity.

The Step 2 gap is structural: convolution with $1/\eta$ (equivalently, with the partition function $p(\cdot)$) destroys eventual periodicity because $p(k) \rightarrow \infty$.

55.4 Verlinde ring shadow obstruction tower structure

The “Verlinde shadow” at bar degree r is the image of the bar complex in the Verlinde ring: $\text{Sh}_r^{\text{Ver}} = (1 + V_1 + \dots + V_n)^r \in \text{Ver}(M(p, q))$, where the sum is over all primaries including the identity.

Computation 55.4 (Verlinde shadows;). The Verlinde shadow grows *exponentially* in bar degree r , governed by the largest eigenvalue $\lambda_{\max}$ of the total fusion matrix $\sum_i N_i$ (the i -th fusion matrix):

$\mathcal{M}(2, 5)$: Verlinde ring $\mathbb{Z}[1, \varphi]/(\varphi^2 = 1 + \varphi)$. For $N_{\text{tot}} = N_1 + N_\varphi$ the matrix in the basis $(1, \varphi)$ is $\begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix}$, with eigenvalues $(3 \pm \sqrt{5})/2$.

$$\text{Sh}_r^{\text{Ver}} = (1 + \varphi)^r \quad \text{reduced by } \varphi^2 = 1 + \varphi.$$

Growth rate: $\lambda_{\max} = (3 + \sqrt{5})/2$.

$\mathcal{M}(3, 4)$ **Ising**: Verlinde ring $\mathbb{Z}[1, \sigma, \varepsilon]/(\sigma^2 = 1 + \varepsilon, \sigma\varepsilon = \sigma, \varepsilon^2 = 1)$. Total fusion matrix eigenvalues: $2 + \sqrt{2} \approx 3.414, 2 - \sqrt{2} \approx 0.586, 0$.

$$\text{Sh}_1 = 1 + \sigma + \varepsilon$$

$$\text{Sh}_2 = 3 \cdot 1 + 4 \sigma + 3 \varepsilon$$

$$\text{Sh}_3 = 10 \cdot 1 + 14 \sigma + 10 \varepsilon$$

Growth rate: $\lambda_{\max} = 2 + \sqrt{2}$.

$\mathcal{M}(3, 5)$: Verlinde ring with four generators $\{1, a, b, c\}$ (conformal weights $0, -1/20, 1/5, 3/4$). Fusion: $a^2 = 1 + b, ab = a + c, b^2 = 1 + b, ac = b, bc = a, c^2 = 1$. Total fusion matrix eigenvalues: $3 + \sqrt{5} \approx 5.236, 3 - \sqrt{5} \approx 0.764, 0, 0$. The coefficient of a equals that of b at every degree.

$$\text{Sh}_r = \alpha_r \cdot 1 + \beta_r (a + b) + \gamma_r c, \quad \alpha_r = \gamma_r, \quad \beta_r/\alpha_r \rightarrow \frac{1+\sqrt{5}}{2} \text{ as } r \rightarrow \infty.$$

Growth rate: $\lambda_{\max} = 3 + \sqrt{5}$.

The Verlinde shadow encodes no periodicity: it grows exponentially with r . The modular periodicity conjecture concerns the conformal-weight grading within fixed r , not the Verlinde level structure.

Remark 55.5 (Quantum dimensions). The growth is controlled by the Perron–Frobenius eigenvalue of the total fusion matrix $N_{\text{tot}} = \sum_i N_i$, not by the global dimension $\sum_i d_i^2$. In a unitary normalization this is the sum of the positive Frobenius–Perron dimensions. For non-unitary models one should compute N_{tot} directly. For $\mathcal{M}(2, 5)$ the total fusion matrix has spectral radius 2. For $\mathcal{M}(3, 4)$: $d_\sigma = -\sqrt{2}, d_\varepsilon = 1$, and the total fusion matrix has spectral radius $2 + \sqrt{2}$.

55.5 Koszul dual character obstruction

Computation 55.6 (Koszul dual character;). For a Koszul chiral algebra $\mathcal{A}$ with vacuum character $h_{\mathcal{A}}(q) = \sum_{k \geq 0} (\dim \mathcal{A}_{[k]}) q^k$, the bar cohomology character is $\sum_{k \geq 0} (\dim H_*(B_{[k]}^{\text{ch}})) q^k = 1/h_{\mathcal{A}}(-q)$.

For $\mathcal{M}(2, 5)$:

$$\begin{aligned} h_{\mathcal{A}}(q) &= 1 + q + 2q^2 + 3q^3 + 5q^4 + 7q^5 + 11q^6 + 15q^7 + \dots \\ 1/h_{\mathcal{A}}(-q) &= 1 + q - q^2 - q^5 - q^7 - q^{12} + q^{15} + q^{17} + q^{18} - q^{19} + \dots \end{aligned}$$

The first ~ 17 nonzero coefficients of $1/h_{\mathcal{A}}(-q)$ are ± 1 , suggesting sparse structure. Beyond $h = 50$, the coefficients grow: by $h = 500$, $|\text{coefficients}|$ reach ~ 9000 .

*The Koszul dual character is **not** eventually periodic.* Its coefficients grow without bound, driven by the non-trivial interaction between the partition-function denominator and the theta-function numerator.

For the Ising model $M(3, 4)$, the same phenomenon occurs: $1/h_{\mathcal{A}}(-q) = 1 + q - q^2 - q^5 - q^7 - q^{12} + q^{15} + \dots$ (identical to Lee–Yang in the first 12 terms, since both have $\dim V_{1,1}[k] = p(k)$ for $k \leq 16$).

This means: if the bar cohomology of the VOA $M(p, q)$ is concentrated in a single degree at each weight (the Koszul property), then the cohomology dimensions are $|\text{coefficients of } 1/h_{M(p,q)}(-q)|$, which grow. **The conjecture as stated fails for the algebraic bar complex of the VOA.**

Remark 55.7 (Resolution of the obstruction). The obstruction applies to the bar complex of the VOA $V = M(p, q)$ viewed as a *single* vertex algebra. The conjecture may still hold in one of the following senses:

- (i) *Categorical bar complex.* The bar complex of the modular tensor category $\text{Rep}(M(p, q))$ involves all $(p-1)(q-1)/2$ simple modules simultaneously, with the bar differential controlled by the modular S -matrix. The semisimplicity of the Verlinde ring means the categorical bar cohomology vanishes above degree 1, but the *weight-graded* structure within each module may exhibit periodicity from the T -matrix.
- (ii) *Normalized periodicity.* The ratio $\dim H^n(B_{[h]}^{\text{ch}})/p(h)$, where $p(h)$ is the partition function, may be eventually periodic. This would be a “periodicity modulo partition growth.”
- (iii) *Euler characteristic periodicity.* The alternating sum $\chi(h) = \sum_n (-1)^n \dim B_{\text{ch},[h]}^{(n)}$ involves massive cancellation and may be periodic even when individual terms are not.

55.6 Reformulation proposal

Based on the computations above, we propose the following reformulation of the modular periodicity conjecture.

Conjecture 55.8 (Modular periodicity, reformulated). Let $M(p, q)$ be a Virasoro minimal model and let $N = N(p, q)$ be the T -matrix order (55.1). Let $d(n, h) = \dim \overline{B}_{\text{ch},[h]}^{(n)}(M(p, q))$ be the chain-space dimension and $\beta(n, h) = \dim H_n(\overline{B}_{[h]}^{\text{ch}}(M(p, q)))$ the cohomology dimension.

- (i) **Euler characteristic periodicity.** The Euler characteristic $\chi(h) = \sum_{n \geq 1} (-1)^n d(n, h)$ satisfies $\chi(h + N) = \chi(h)$ for all $h \gg 0$.
- (ii) **Cohomological periodicity modulo partition growth.** There exist polynomials $P_n(h)$ and periodic functions $\pi_n(h)$ of period N such that $\beta(n, h) = P_n(h) + \pi_n(h)$ for all $h \gg 0$. The periodic part π_n is determined by the modular data (S, T) .
- (iii) **T -matrix period correction.** The period N in all three conjectures (Conjectures ??, ??, ??) should be replaced by (55.1).

Question 55.9. Does the weight-graded bar complex of the *fusion category* $\text{Rep}(M(p, q))$ -- as opposed to the bar complex of the VOA $M(p, q)$ -- exhibit exact periodicity in conformal weight? The categorical Hochschild cohomology of a fusion category is known to be finite-dimensional; does its weight grading recover the T -matrix period?

Question 55.10. What is the relationship between the T -matrix period $N(p, q)$ and the order of the image of $\text{SL}(2, \mathbb{Z})$ in the modular representation on the character space? The kernel of the modular representation contains the principal congruence subgroup $\Gamma(N)$, so the image has order dividing $|\text{SL}(2, \mathbb{Z}/N\mathbb{Z})| = N^3 \prod_{p|N} (1 - 1/p^2)$. For $M(2, 5)$: $N = 60$, image order divides $|A_5| \cdot 2 = 120$. Is the image always a central extension of a permutation group related to the Galois action on the primaries?

Remark 55.11 (Connection to the Koszul dual). For the *reflected* modular periodicity (Conjecture ??): the Koszul dual of Vir_c is Vir_{26-c} . For $M(2, 5)$: $c = -22/5$, $c' = 152/5$. The dual central charge $c' = 152/5$ is *not* a minimal model value (it requires $1 - 6(p - q)^2/(pq) = 152/5$, which has no solution in coprime integers). Therefore the reflected periodicity conjecture requires either:

- (i) a definition of modular period for non-rational VOAs (extending beyond the minimal model setting), or
- (ii) restriction to models where both c and $26 - c$ are minimal model central charges (a very sparse set).

56 Gravitational Yangian: explicit generators and relations

This section computes the explicit generators and relations of the gravitational Yangian $Y^{\text{dg}}(\text{Vir}_c)$: the E_1 -ordered face of the Swiss-cheese algebra for the Virasoro boundary. The inputs are:

- (1) the Virasoro λ -bracket $\{T_\lambda T\} = \partial T + 2T\lambda + \frac{c}{12}\lambda^3$;
- (2) the collision residue $r^{\text{coll}}(z) = (c/2)/z^3 + 2T/z$ (bar-theoretic, pole orders one lower than the OPE via $d \log$ absorption);
- (3) the gravitational coproduct primitivity: $\Delta_z(x) = \tau_z(x) \otimes 1 + 1 \otimes x$ for all x in the Virasoro sector, at every arity;
- (4) the Koszul dual identification $\text{Vir}_c^\dagger = \text{Vir}_{26-c}$.

56.1 The generator space

The gravitational Yangian lives on the Koszul dual $\text{Vir}_{c'} = \text{Vir}_{26-c}$, with generators $\{L_n\}_{n \in \mathbb{Z}}$ satisfying

$$[L_m, L_n] = (m - n) L_{m+n} + \frac{c'}{12}(m^3 - m) \delta_{m+n,0}, \quad c' := 26 - c. \quad (22)$$

The r -matrix on $\text{Vir}_{c'}^{\widehat{\otimes} 2}$ is

$$r(z) = \sum_{m \geq 0} \frac{\Omega_m}{z^{m+1}}, \quad \Omega_m = \sum_{n \in \mathbb{Z}} \binom{n+m-1}{m} L_{-n-m} \otimes L_n.$$

The first three Casimir components:

$$\begin{aligned} \Omega_0 &= \sum_{n \in \mathbb{Z}} L_{-n} \otimes L_n, \\ \Omega_1 &= \sum_{n \in \mathbb{Z}} n L_{-n-1} \otimes L_n, \\ \Omega_2 &= \sum_{n \in \mathbb{Z}} \frac{n(n+1)}{2} L_{-n-2} \otimes L_n. \end{aligned}$$

Definition 56.1 (Level- r Yangian generators). The *level- r generators* of $Y^{\text{dg}}(\text{Vir}_c)$ are the modes $T_n^{(r)}$ defined by expanding Ω_r in the first tensor factor:

$$\Omega_r = \sum_{n \in \mathbb{Z}} T_n^{(r)} \otimes L_n, \quad T_n^{(r)} = \binom{n+r-1}{r} L_{-n-r}.$$

At level 0: $T_n^{(0)} = L_{-n}$. At level 1: $T_n^{(1)} = n L_{-n-1}$. At level 2: $T_n^{(2)} = \frac{n(n+1)}{2} L_{-n-2}$.

Equivalently, define the generating functions

$$T^{(r)}(u) := \sum_{n \in \mathbb{Z}} T_n^{(r)} u^{-n-1} = \sum_{n \in \mathbb{Z}} \binom{n+r-1}{r} L_{-n-r} u^{-n-1}.$$

Remark 56.2 (Level 0 generates the Virasoro subalgebra). At level 0, the generating function is $T^{(0)}(u) = \sum_{n \in \mathbb{Z}} L_{-n} u^{-n-1} = T(u)$, the stress-energy tensor field of $\text{Vir}_{c'}$. The level-0 modes $T_n^{(0)} = L_{-n}$ satisfy the Virasoro algebra (56.1) with central charge c' . This is the Virasoro subalgebra at the dual central charge $c' = 26 - c$.

56.2 The level-0–level-1 commutation relation

PROPOSITION 56.3 (*Level-0–level-1 bracket; proved here*). The commutator of a level-0 generator $T_m^{(0)} = L_{-m}$ with a level-1 generator $T_n^{(1)} = n L_{-n-1}$ is

$$[T_m^{(0)}, T_n^{(1)}] = n(n+1-m) L_{-(m+n)-1} - \frac{c'}{12} m(m^2-1) n \delta_{m+n+1,0}.$$

Proof. Compute directly: $[T_m^{(0)}, T_n^{(1)}] = n [L_{-m}, L_{-n-1}]$. By the Virasoro relation with $a = -m, b = -n-1$: $a-b = n+1-m, a^3-a = -(m^3-m)$, giving

$$[T_m^{(0)}, T_n^{(1)}] = n(n+1-m) L_{-(m+n)-1} - \frac{c'}{12} m(m^2-1) n \delta_{m+n+1,0}.$$

The relation does NOT close within levels 0 and 1: the generator $L_{-(m+n)-1}$ can be expressed as a level-1 generator only when $m+n \neq 0$. $\square$

Remark 56.4 (Comparison with the affine Yangian). For the affine Kac–Moody case $\widehat{\mathfrak{g}}_k$, the level-0–level-1 relation is $[J^{a,(0)}, J^{b,(1)}] = f_c^{ab} J^{c,(1)}$: the level-1 generators form a representation of the level-0 Lie algebra. For the gravitational Yangian, the analogous relation has the same structure -- the level-1 generators $n L_{-n-1}$ transform under the adjoint action of $\text{Vir}_{c'}$ -- but with the crucial difference that the central extension contributes a scalar term proportional to c' .

56.3 The level-1–level-1 commutation relation

THEOREM 56.5 (*Level-1–level-1 bracket; proved here*). The commutator of two level-1 generators is

$$[T_m^{(1)}, T_n^{(1)}] = mn(n-m) L_{-m-n-2} - \frac{c'}{12} mn ((m+1)^3 - (m+1)) \delta_{m+n+2,0}.$$

Proof. Compute: $[T_m^{(1)}, T_n^{(1)}] = mn [L_{-m-1}, L_{-n-1}]$. Set $a = -m-1, b = -n-1$: $a-b = n-m, a^3-a = -(m+1)^3 + (m+1)$, giving

$$[L_{-m-1}, L_{-n-1}] = (n-m) L_{-m-n-2} - \frac{c'}{12} ((m+1)^3 - (m+1)) \delta_{m+n+2,0}.$$

Hence $[\mathsf{T}_m^{(1)}, \mathsf{T}_n^{(1)}] = mn[(n-m)L_{-m-n-2} - \frac{c'}{12}((m+1)^3 - (m+1))\delta_{m+n+2,0}]$. Skew-symmetry: under $m \leftrightarrow n$ with $n = -m-2$, $((n+1)^3 - (n+1)) = -((m+1)^3 - (m+1))$, confirming consistency. $\square$

Remark 56.6 (The level-1 bracket does not close). The right-hand side involves L_{-m-n-2} , a level-o generator $\mathsf{T}_{m+n+2}^{(o)}$. The bracket $[\mathsf{T}^{(1)}, \mathsf{T}^{(1)}]$ produces generators at level o. This is the fundamental difference from the affine KM Yangian where $[J^{a,(1)}, J^{b,(1)}]$ produces a level-1 generator plus a level-o correction.

56.4 The general level- r -level- s relation

THEOREM 56.7 (*General bracket; proved here*). For arbitrary levels $r, s \geq 0$:

$$[\mathsf{T}_m^{(r)}, \mathsf{T}_n^{(s)}] = \binom{m+r-1}{r} \binom{n+s-1}{s} \left[(n+s-m-r)L_{-m-n-r-s} - \frac{c'}{12}((m+r)^3 - (m+r))\delta_{m+n+r+s,0} \right].$$

Proof. By definition, $\mathsf{T}_m^{(r)} = \binom{m+r-1}{r} L_{-m-r}$ and $\mathsf{T}_n^{(s)} = \binom{n+s-1}{s} L_{-n-s}$. The bracket reduces to a Virasoro commutator with $a = -m-r$, $b = -n-s$. $\square$

Remark 56.8 (Why the Virasoro gravitational Yangian is NOT a standard Yangian). The gravitational Yangian differs from a standard Yangian $Y(\mathfrak{g})$ in three essential ways:

- (i) *All levels are dependent.* $\mathsf{T}_n^{(r)} = \binom{n+r-1}{r} L_{-n-r}$ is a scalar multiple of a single Virasoro generator. There is no independent level-1 generator.
- (ii) *The bracket between levels produces lower levels.* $[\mathsf{T}^{(r)}, \mathsf{T}^{(s)}]$ is proportional to a single Virasoro mode $L_{-m-n-r-s}$, expressible as a level-o generator.
- (iii) *Infinite non-formality replaces deformation.* The Yangian structure is encoded in the $\mathcal{A}_\infty$ tower $\{m_k\}_{k \geq 3}$, not in independent generators. The r -matrix $r(z) = \sum_{m \geq 0} \Omega_m z^{-m-1}$ has infinitely many poles, all determined by the single Virasoro λ -bracket.

56.5 Formal collision-kernel identity

PROPOSITION 56.9 (*Collision-kernel identity on completed modules*). On a chosen completed Virasoro module on which the sums Ω_r are defined, the transfer kernel $T_V(z) = \sum_{r \geq 0} z^{-r-1} \pi_V(\Omega_r)$ satisfies the formal collision identity

$$r_{12}(z_1 - z_2) T_1(z_1) T_2(z_2) = T_2(z_2) T_1(z_1) r_{12}(z_1 - z_2),$$

only after the simple-pole/fundamental reduction. In the full gravitational setting the higher-pole Virasoro collision kernel gives a four-term completed-module identity, not a standard FRT or RTT presentation.

56.6 Structure theorem

PROPOSITION 56.10 (*Formal structure of $Y^{\text{dg}}(\text{Vir}_c)$*). The gravitational Yangian has the following dg-shifted bialgebra structure:

- (i) *As a Lie algebra*, $Y^{\text{dg}}(\text{Vir}_c) \cong \text{Vir}_c$: all level- r generators are linearly dependent on level-o.

- (ii) *As a dg-shifted bialgebra*, the additional structure is the infinite A_∞ product tower $\{m_k^{\text{Vir}}\}_{k \geq 3}$, the primitive coproduct, and the higher-pole r -matrix. No antipode/Hopf structure is asserted.
- (iii) *The A_∞ corrections* (quartic contact $10/[c(5c + 22)]$, quintic, etc.) are contact and shadow corrections. Identifying them with physical scattering amplitudes requires additional analytic input.
- (iv) *The deformation is $U(\text{Vir}_{c'})$ with A_∞ corrections*: a curved A_∞ -deformation, NOT a filtered deformation of $U(\text{Witt}[t])$.

Proof. (i) from $T_n^{(r)} = \binom{n+r-1}{r} L_{-n-r}$. (ii) from the dg-shifted Yangian recognition theorem. (iii) from the 3d gravity movements. (iv) from non-existence of the standard Yangian deformation. $\square$

56.7 Summary and comparison table

	Standard Yangian $Y(\mathfrak{g})$	Gravitational Yangian $Y^{\text{dg}}(\text{Vir}_c)$
Generator space	$\mathfrak{g}$ (level 0) $\oplus$ $\mathfrak{g}$ (level 1)	$\text{Vir}_{c'}$ (all levels dependent)
Presentation	Finitely presented (Drinfeld or RTT)	Formal collision-kernel identities; no standard RTT presentation
Level-1-1 bracket	$[\hat{f}^a, \hat{f}^b] = f_c^{ab} \hat{f}^c + \alpha^2$ (cubic Casimir)	$[\tau_m^{(1)}, \tau_n^{(1)}] = mn(n-m) L_{-m-n-2} - \frac{c}{12} mn((m+1)^3 - (n+1)^3) \delta_{m+n+2,0}$
Coproduct	Nontrivial	Strictly primitive
r -matrix	Simple pole: $r(z) = k \Omega/z$ (trace convention)	Infinite poles: $r(z) = \sum_{m \geq 0} \Omega_m z^{-m-1}$
Deformation	Filtered deformation of $U(\mathfrak{g}[t])$	Curved A_∞ -deformation of $U(\text{Vir}_{c'})$

Observation 56.11 (The gravitational Yangian is the Virasoro algebra in disguise). The gravitational Yangian $Y^{\text{dg}}(\text{Vir}_c)$ has no independent “Yangian partner” generator. The Lie-algebraic content is exactly $\text{Vir}_{c'}$; what makes it a dg-shifted Yangian rather than a plain Lie algebra is the infinite A_∞ product tower $\{m_k\}_{k \geq 3}$ and the higher-pole r -matrix. The gravitational Yangian is the Virasoro algebra with the A_∞ shadow obstruction tower exposed.

Question 56.12 (Curved A_∞ and the deformed Virasoro). The deformed Virasoro algebra $\text{Vir}_{q,t}$ of Shiraishi–Kubo–Awata–Odake is a two-parameter deformation. The gravitational Yangian is a one-parameter (c) curved A_∞ -deformation. Is there a precise relationship? The natural conjecture: $Y^{\text{dg}}(\text{Vir}_c)$ is the classical limit ($q \rightarrow 1$) of a quantized gravitational Yangian whose underlying algebra is $\text{Vir}_{q,t}$.

57 Kontsevich integral from the bar complex: trefoil checks

57.1 Setup and notation

The Kontsevich integral $Z(K)$ of a framed knot $K : S^1 \rightarrow \mathbb{C} \times \mathbb{R}$ is the universal Vassiliev invariant:

$$Z(K) = \sum_{n=0}^{\infty} \frac{1}{(2\pi i)^n} \int_{t_{\min} < t_1 < \dots < t_n < t_{\max}} \sum_P \bigwedge_{(i,j) \in P} d \log(z_i(t_i) - z_j(t_j)) \cdot D_P, \quad (23)$$

valued in the completed algebra of chord diagrams $\widehat{\mathcal{A}}(\mathfrak{g})$. For the trefoil $K = 3_1$, we verify this against the bar complex $\overline{B}(\widehat{\mathfrak{sl}}_{2k})$.

The bar-complex R -matrix. For $\mathfrak{g} = \mathfrak{sl}_2$ at level $k \neq -h^\vee = -2$, the spectral r -matrix from the bar complex (Proposition ?? of spectral-braiding-core) is

$$r(z) = \frac{k \Omega}{z},$$

where $\Omega = \kappa^{IJ} t_I \otimes t_J = \frac{1}{2}(H \otimes H + 2E \otimes F + 2F \otimes E)$ is the $\mathfrak{sl}_2$ Casimir tensor (normalised so that $C_2(\text{adj}) = 2h^\vee = 4$ and $C_2(\text{fund}) = 3/4$). The full quantum R -matrix is $R(z) = \exp(\hbar r(z)) = \exp(\hbar k \Omega/z)$, with $\hbar$ the loop parameter.

The trefoil as a braid closure. The trefoil is the closure of $\sigma_1^3 \in B_2$, the three-fold positive braid generator in the two-strand braid group. In the bar-complex formulation, the Kontsevich integral of a braid $\beta \in B_n$ on n strands is computed by n -fold parallel line operators with the R -matrix acting at each crossing. For the trefoil:

$$Z(3_1) = \text{tr}_M(R(z_{12})^3),$$

where the trace is the Markov trace implementing braid closure. At the level of chord diagrams (before evaluating on a weight system), this becomes a formal exponential.

57.2 Degree-1 verification (the chord diagram θ)

At degree $n = 1$, the Kontsevich integral has one chord connecting two points on the knot at heights $t_1 < t_2$. The single chord diagram of degree 1 is θ (a single chord connecting two points on the knot).

For a general knot K presented as the closure of $\sigma_1^w \in B_2$:

$$Z_1(K) = \frac{w}{2\pi i} \int d \log(z_1(t_1) - z_2(t_2)) \cdot \theta = \frac{w}{2} \theta,$$

where w is the writhe (the signed crossing number; $w = 3$ for the trefoil). The coefficient $w/2$ arises from the $d \log$ integral: for a single crossing at height t_* , $\frac{1}{2\pi i} \int d \log(z_1 - z_2)$ around the crossing gives $\pm 1/2$ per crossing, summed over w crossings.

From the bar complex: the degree-1 contribution is $\hbar r(z)$ composed three times and traced. At order $\hbar$, this gives $3 \cdot r(z_{12})$, integrated over the configuration. The coefficient matches: $3/2 = w/2$ for $w = 3$.

Remark 57.1 (Framing correction). The degree-1 term is framing-dependent. The “framed” Kontsevich integral $\hat{Z}(K)$ divides by $Z(\text{unknot with framing } w) = \exp(w \theta/2)$, so $\hat{Z}_1(3_1) = 0$ after framing correction. The nontrivial content starts at degree 2.

57.3 Degree-2 verification: the coefficient $z_2(3_1) = 1/24$

This is the central computation. The degree-2 Kontsevich invariant $z_2(K)$ is the first nontrivial Vassiliev invariant (after framing correction), and for the trefoil it takes the value $z_2(3_1) = 1/24$.

57.3.1 Step 1: The R-matrix in the fundamental representation

In the fundamental representation $V = \mathbb{C}^2$ of $\mathfrak{sl}_2$, the Casimir tensor acts as

$$\Omega|_{V \otimes V} = \frac{1}{2}(P - \frac{1}{2} \text{id}),$$

where P is the permutation operator $P(v \otimes w) = w \otimes v$. Explicitly, $C_2(\text{fund}) = 3/4$, and $\Omega = \frac{1}{2}(P - \frac{1}{2} \text{id})$ acts with eigenvalue $1/4$ on the symmetric part $\text{Sym}^2(V)$ and eigenvalue $-3/4$ on the antisymmetric part $\Lambda^2(V)$.

The quantum R -matrix $R = \exp(\hbar k \Omega / z)$ on $V \otimes V$ therefore decomposes:

$$R|_{\text{Sym}^2(V)} = e^{\hbar k / (4z)}, \quad R|_{\Lambda^2(V)} = e^{-3\hbar k / (4z)}.$$

57.3.2 Step 2: The braid representation

The trefoil 3_1 is the closure of σ_1^3 , so R is applied three times:

$$R^3|_{\text{Sym}^2} = e^{3\hbar k / (4z)}, \quad R^3|_{\Lambda^2} = e^{-9\hbar k / (4z)}.$$

The Markov trace (quantum trace) on $V \otimes V$ is

$$\text{tr}_q(X) = \text{tr}(q^{2\rho} X),$$

where $q^{2\rho} = \text{diag}(q, q^{-1})$ on V . For the trefoil at generic q (which we expand perturbatively), the unnormalised leading trace is:

$$Z_V^{\text{unnorm}}(3_1) = \text{tr}_q(R^3) = 3 \cdot e^{3\hbar k / (4z)} + 1 \cdot e^{-9\hbar k / (4z)},$$

where the factors $3 = \dim(\text{Sym}^2 V)$ and $1 = \dim(\Lambda^2 V)$ arise from the quantum trace (at leading order in q). The normalized Kontsevich/Jones quantity divides by the quantum dimension of the unknot and applies the framing correction; the unnormalised trace is not itself a partition function with constant term 1.

57.3.3 Step 3: Expansion in chord diagrams

To extract the universal (weight-system-independent) Vassiliev invariant z_2 , we work in the chord diagram algebra before evaluating on the $\mathfrak{sl}_2$ weight system.

The perturbative expansion of $R^3 = \exp(3\hbar r(z))$ at the level of chord diagrams is:

$$\begin{aligned} R^3 &= \exp(3\hbar k \Omega / z) \\ &= \text{id} + 3\hbar k \Omega / z + \frac{1}{2}(3\hbar k / z)^2 \Omega^2 + O(\hbar^3). \end{aligned}$$

The degree-2 contribution to the Kontsevich integral involves integrating $(3\hbar k / z)^2 \Omega^2 / 2$ over the configuration space, combined with the degree-2 connected contribution.

At degree 2, the Kontsevich integrand for the trefoil has three types of chord diagrams (parallel, crossed, nested), as established in the order-2 matching (Proposition ??). We now compute the coefficient from the braid closure.

57.3.4 Step 4: Integration over the trefoil configuration

The trefoil has 3 positive crossings. At each crossing, the d log form contributes winding number $+1$. The degree-2 Kontsevich integral sums over pairs of crossings among the 3 crossings: there are $\binom{3}{2} = 3$ such pairs.

For the disconnected contribution (two independent chords at different crossings), we get

$$Z_2^{\text{disc}}(3_1) = \frac{1}{2} (Z_1(3_1))^2 = \frac{1}{2} \cdot \frac{9}{4} \theta^2 = \frac{9}{8} \theta^2,$$

where $Z_1(3_1) = \frac{3}{2} \theta$ from the degree-1 computation.

The connected contribution requires the integral of the degree-2 logarithmic form over the trefoil's specific geometry. For the trefoil presented as the $(2, 3)$ torus knot with parametrization $z(t) = e^{3it}$, $w(t) = e^{2it}$ (two strands, $t \in [0, 2\pi]$), the connected degree-2 integral is computed via the Bar-Natan formula [BarNatan95].

Computation 57.2 (The connected degree-2 normalization for the trefoil; conditional on standard Kontsevich normalization). The writhe-corrected degree-2 invariant is

$$c_2(3_1) = z_2(3_1) - \frac{1}{2} z_1(3_1)^2 + \frac{w^2}{24} \theta^2,$$

where the “ $w^2/24$ ” term is the framing correction. Equivalently, after dividing by the unknot with writhe $w = 3$:

$$v_2(3_1) = 1,$$

and $z_2(3_1) = v_2(3_1)/24 = 1/24$ in the standard normalisation where z_2 is the second coefficient of the logarithm of $Z(K)$.

Compatibility check from the bar complex. We check that the bar-complex expression has the correct connected degree-2 shape for $\overline{B}(\widehat{\mathfrak{sl}}_{2,k})$. The numerical equality $z_2(3_1) = 1/24$ is the Bar–Natan/Kontsevich normalization input, not an independent evaluation of the compactified configuration-space integral here.

Step A: Bar-complex R-matrix for the trefoil. The trefoil is the closure of σ_1^3 . The bar complex produces the R -matrix $R(z) = \exp(\hbar k \Omega/z)$ as a formal exponential in chord diagrams. The braid closure gives

$$Z(3_1) = \text{tr}_M(R(z_{12})^3),$$

the Markov trace of the braid product, not a tensor-power trace. The perturbative expansion in $\hbar$ extracts the Vassiliev invariants.

Step B: Degree-2 extraction. The degree-2 Vassiliev invariant is extracted from the $\hbar^2$ coefficient of $\log Z(3_1)$. The logarithm removes the disconnected (product) contributions:

$$\log Z(3_1) = \sum_{n \geq 1} z_n(3_1) \cdot D_n,$$

where D_n is the degree- n chord diagram monomial.

At degree 2, the connected contribution comes from two sources in the bar complex:

- (i) The *double collision* at the same crossing: two d log forms are wedged at a single crossing point, giving a contribution from $\text{FM}_2(\mathbb{C})$ at the triple-collision boundary.
- (ii) The *single collision at two different crossings*: the product of two degree-1 terms, which contributes to the disconnected part (subtracted by log).

With the standard Kontsevich normalization fixed, the connected degree-2 contribution after the logarithm is

$$z_2(3_1) = \frac{1}{(2\pi i)^2} \int_{\substack{t_1 < t_2 < t_3 < t_4 \\ \text{along } 3_1}} \omega_P^{\text{conn}} \cdot D_P = \frac{1}{24} D_2^{\text{conn}},$$

where D_2^{conn} denotes the connected degree-2 chord-diagram class in the chosen normalization.

Step C: Matching with the η -function/ κ relation. The coefficient $1/24$ arises in the bar complex from the modular characteristic $\kappa(\mathcal{H}_k) = k$ of the Heisenberg algebra. The genus-1 free energy is

$$F_1 = -\kappa \log \eta(\tau) = -k \log \eta(\tau).$$

The leading q -exponent coefficient of F_1 is $-k/24$. For the trefoil, the three crossings each contribute a factor of k from the Casimir. The remaining scalar is the normalized Kontsevich/Bar–Natan degree-2 integral:

$$z_2(3_1) = (\text{bar Casimir factor}) \cdot (\text{normalized degree-2 Kontsevich integral}) = \frac{1}{24} D_2^{\text{conn}}.$$

The $1/24$ is not a coincidence: both the genus-1 free energy and the trefoil’s degree-2 Vassiliev invariant are controlled by the same Arnold defect on the configuration space, reflected in the Bernoulli number $B_2 = 1/6$ via $1/24 = B_2/4 = 1/(4 \cdot 6)$.

Step D: Weight-system status. The $\mathfrak{sl}_2$ weight-system evaluation depends on the chosen normalization of the connected degree-2 chord class D_2^{conn} . It is not used here as an independent numerical verification of the universal coefficient. $\square$

Remark 57.3 (The coefficient $1/24$ and the Dedekind η -function). The appearance of $1/24$ in the trefoil’s degree-2 Vassiliev invariant, in the genus-1 free energy $F_1 = -k \log \eta(\tau)$ through its leading q -exponent coefficient $-k/24$, and in the Bernoulli number $B_2/4$ is a manifestation of a single phenomenon: the obstruction class on $\text{FM}_2(\mathbb{C}) \times \text{Conf}_2(\mathbb{R})$ is controlled by the first non-trivial Bernoulli number.

In the bar complex, this is the degree-2 component of $d_{\bar{B}}^2 = \kappa(\mathcal{A}) \omega_1$: at genus 1, the curved bar structure deforms the differential by $\kappa \omega_1$, and the perturbative coefficient of ω_1 in the Eisenstein basis is $-1/24$ (the constant term of the holomorphic Eisenstein series $G_2(\tau) = -1/24 + \sum_{n \geq 1} \sigma_1(n) q^n$).

The trefoil, as the simplest nontrivial knot, probes exactly this first modular defect: the three crossings of σ_1^3 give the minimal nontrivial configuration on $\text{FM}_2(\mathbb{C}) \times \text{Conf}_2(\mathbb{R})$.

57.4 Degree-3 verification: IHX from m_3 and the Arnold identity

At degree $n = 3$, the Kontsevich integral sums over 15 chord diagrams (perfect matchings of 6 points on the knot). The IHX relation reduces these to a one-dimensional space for the $\mathfrak{sl}_2$ weight system.

57.4.1 Step 1: The role of m_3 for $\widehat{\mathfrak{sl}}_{2,k}$

For the affine lineage, one-loop exactness (Theorem ??) gives vanishing of the transferred cohomology operations m_k^H for $k \geq 3$. Therefore, the degree-3 bar differential $d_{\overline{B}}^{(3)}$ on $\mathrm{FM}_3(\mathbb{C})$ involves *only* pairwise collisions (iterated m_2 compositions), never a simultaneous 3-fold collision requiring m_3 . This is the crucial simplification that makes the Kontsevich framework applicable: the chord diagram algebra captures exactly the pairwise interaction structure of the one-loop-exact bar complex.

Remark 57.4 (Why cohomological m_3 -vanishing matters). If $m_3 \neq 0$ (as for the Virasoro algebra or non-formal Swiss-cheese structures), the degree-3 bar differential would include trivalent vertices, and the appropriate target would be the *Jacobi diagram algebra* rather than the chord diagram algebra. The Kontsevich integral, as defined by (57.1), uses only pairwise $d \log$ forms and thus sees only the chord diagram quotient. The higher m_k contributions are invisible to the classical Kontsevich framework; capturing them requires the full A_∞ partition function $Z_{A_\infty}(K)$.

57.4.2 Step 2: The Arnold relation implies IHX

On $\mathrm{FM}_3(\mathbb{C})$ with three marked points, the cohomology ring $H^\bullet(\mathrm{Conf}_3(\mathbb{C}))$ satisfies the Arnold relation:

$$\alpha_{12} \wedge \alpha_{23} + \alpha_{23} \wedge \alpha_{31} + \alpha_{31} \wedge \alpha_{12} = 0, \quad \alpha_{ij} = [d \log(z_i - z_j) / (2\pi i)].$$

Decorating with $\mathfrak{g}$ -valued Casimir insertions and interpreting via the bar complex:

$$\begin{aligned} \alpha_{12} \wedge \alpha_{23} &\longleftrightarrow D_I \text{ (I-diagram),} \\ \alpha_{23} \wedge \alpha_{31} &\longleftrightarrow D_H \text{ (H-diagram),} \\ \alpha_{31} \wedge \alpha_{12} &\longleftrightarrow D_X \text{ (X-diagram).} \end{aligned}$$

The Arnold–Orlik–Solomon relation gives the $4T$ relation in the chord-diagram algebra. Via the STU bridge it induces the IHX relation in the Jacobi/trivalent diagram lane. The relative signs come from orientation reversal on the boundary strata of $\mathrm{FM}_3(\mathbb{C})$.

57.4.3 Step 3: The unique degree-3 $\mathfrak{sl}_2$ invariant

The IHX relation reduces the space of connected degree-3 chord diagrams evaluated on $\mathfrak{sl}_2$ to dimension 1. The unique invariant is the “wheel” w_3 , computed by

$$w_3 = \sum_{a,b,c} f^{abc} f^{abc} = 2 C_2(\mathrm{adj}) = 2 \cdot 4 = 8 \quad \text{for } \mathfrak{sl}_2,$$

where $C_2(\mathrm{adj}) = 2h^\vee = 4$. In the bar complex, this comes from the triple collision stratum $D_{\{1,2,3\}}$ of $\mathrm{FM}_3(\mathbb{C})$: the iterated commutator $[[\Omega_{12}, \Omega_{23}], \Omega_{13}]$ evaluated as $\sum f^{abc} f^{abc} = w_3$.

The numerical coefficient requires a specified top cycle, orientation, and normalization convention on the compactified configuration space; no definite FM_3 integral is asserted here.

57.4.4 Step 4: Degree-3 coefficient for the trefoil

For the trefoil (three crossings, writhe $w = 3$), the degree-3 Vassiliev invariant (after framing correction) is

$$v_3(3_1) = 1,$$

corresponding to $z_3(3_1) = v_3/(3! \cdot 4) = 1/24$ in the normalisation where z_n is the n -th coefficient of $\log Z(K)$ (we use the standard Chmutov–Duzhin–Mostovoy conventions [?CDM12]).

At degree 3 the Arnold relation gives the IHX structure in the bar complex. Matching the full coloured-Jones coefficient requires a separate normalization of the degree-3 weight-system class and is treated here as structural evidence, not as an unconditional numerical verification.

57.5 Summary of the verification

Degree	Bar complex	Kontsevich	Match?	Source
0	I	I	✓	Trivial (empty diagram)
1	$\frac{3}{2} \theta$	$\frac{3}{2} \theta$	✓	Writhe = 3, single Casimir
2	$\frac{1}{24} D_2^{\text{conn}}$	$\frac{1}{24} D_2^{\text{conn}}$	conditional	Normalization 57.2
3	IHX class	$Z_3(3_1)$	structural	Arnold/IHX, §57.4

The key findings:

- (i) The degree-2 coefficient $z_2(3_1) = 1/24$ is compatible with the bar complex of $\widehat{\mathfrak{sl}}_{2,k}$ after the standard Kontsevich/Bar–Natan normalization is fixed. The $1/24$ is not independently derived here from a top-cycle integral.
- (ii) The same $1/24$ is the leading q -exponent coefficient in the genus-1 free energy $F_1 = -k \log \eta(\tau)$; both are manifestations of the curved bar structure $d_{\overline{B}}^2 = \kappa \omega_1$. This supplies a normalization check, not an independent theorem.
- (iii) At degree 3, the IHX relation is derived from the Arnold relation on $\text{FM}_3(\mathbb{C})$ (not imposed by hand), and the vanishing of the transferred cohomology operation m_3^H for the affine lineage ensures compatibility with the chord-diagram formalism.
- (iv) The degree-2 coefficient is conditional on the stated normalization. Degree 3 supplies Arnold/IHX structural evidence; the numerical weight-system normalization is not used as an independent theorem here. The full identification $Z_{A_\infty}(K) = Z(K)$ at all orders remains conjectural (Theorem ??).

Question 57.5 (Degree 4 and beyond). At degree $n = 4$, the chord diagram algebra $\mathcal{A}_4(\mathfrak{sl}_2)$ has dimension 3 (after IHX). The bar complex produces all three independent invariants from iterated pairwise collisions on $\text{FM}_4(\mathbb{C})$. Does the topological integration over $\text{Conf}_4(\mathbb{R})$ for the trefoil match $Z_4(3_1)$?

The degree-4 computation is the first order where the “symmetry factor matching” required by Remark ?? becomes genuinely nontrivial: the normalisation $1/n!$ in (??) versus $1/(2\pi i)^n$ in (57.1) involves a combinatorial identity relating FM boundary strata counts to chord diagram multiplicities. Verifying this identity at $n = 4$ would provide strong evidence for the full conjecture.

58 The cyclic pairing invariant: first explicit computation

The genus-1 modular characteristic $\kappa(\mathcal{A}) = \sum_a \langle e_a, e^a \rangle_{\mathcal{A}}$ -- the self-contraction trace of the unique tadpole graph evaluated on the cyclic pairing -- is computed for every family in the standard HT landscape. For the $\mathcal{M}2$ -brane double-loop algebra $\mathcal{A}_{\mathcal{M}2,\infty}$ (Costello’s DDCA), the infinite generator set $\{E_{\alpha\beta}^{(m,n)}\}$ forces the trace to be an infinite sum requiring regularization. This section performs that regularization via spectral ζ -function techniques and identifies the physical content of the result.

58.1 Review: the standard landscape

The modular characteristic $\kappa(\mathcal{A}) = \sum_i \eta^{ii} R_{ii}$ where $R_{ii} = (a_i)_{(2h_i-1)}(a_i)$ is the leading scalar self-OPE coefficient and η^{ii} is the inverse cyclic pairing for generator a_i .

Family	Generators	$\kappa(\mathcal{A})$	$F_1 = \kappa/24$
$\mathcal{H}_k$	J (wt 1)	k	$k/24$
$\widehat{\mathfrak{sl}}_{2k}$	J^a ($a = 1, 2, 3$; wt 1)	$3(k+2)/4$	$(k+2)/16$
Vir_c	T (wt 2)	$c/2$	$c/48$
$\mathcal{W}_{3c}$	T (wt 2), W (wt 3)	$5c/6$	$5c/144$
$\mathcal{W}_{Nc}$	W_s ($s = 2, \dots, N$)	$c(H_N - 1)$	$c(H_N - 1)/24$
$\beta\gamma$	β, γ (wt 1, 0)	-2	$-1/12$

Here $H_N = \sum_{s=1}^N 1/s$ is the N -th harmonic number. Each line is computed from first principles in `compute/lib/genus1_kappa_verification.py`.

58.2 The cyclic pairing on $\mathcal{A}_{M_2, \infty}$

The generators of the DDCA are $E_{\alpha\beta}^{(m,n)} = E_{\alpha\beta} z^m \partial^n$ at conformal weight $h = m + n + 1$ (see §?? of the extensions chapter). The weight- w subspace $\mathfrak{a}_w = \bigoplus_{m+n=w} \mathbb{k}\{E_{\alpha\beta}^{(m,n)}\}$ has dimension $K^2(w+1)$.

The cyclic pairing on $\mathcal{A}_{M_2, \infty}$ arises from the BV structure of the ambient five-dimensional non-commutative Chern–Simons theory. The BV inner product on the fields $\Phi = \sum_{m,n} a_{\alpha\beta}^{(m,n)} E_{\alpha\beta}^{(m,n)}$ is

$$\langle \Phi_1, \Phi_2 \rangle_{\text{BV}} = \int_{\mathbb{C}} \text{Tr}_K(\Phi_1 \star \Phi_2) dz \wedge d\bar{z},$$

where $\star$ is the Moyal product and Tr_K is the matrix trace. The integration over $\mathbb{C}$ pairs z^m with $\bar{z}^{m'}$ via the standard Gaussian measure (in the Ω -background regularization) and ∂^n with $\bar{\partial}^{n'}$.

The key fact is that in the holomorphic sector (after passing to the chiral algebra via BV-BRST reduction), the cyclic pairing reduces to the *Weyl trace*: the unique trace on $\text{Diff}(\mathbb{C})$ is the evaluation at the origin of the Weyl symbol. Concretely, for monomials in the Weyl algebra $\mathcal{W}_1 = \mathbb{C}\langle z, \partial \rangle / ([\partial, z] = 1)$:

$$\text{tr}_{\text{Weyl}}(z^m \partial^n) = \delta_{m,0} \delta_{n,0}.$$

This is the only continuous trace on $\text{Diff}(\mathbb{C})$ (Fedosov–Nest–Tsygan). Therefore:

$$\langle E_{\alpha\beta}^{(m,n)}, E_{\gamma\delta}^{(p,q)} \rangle_{\text{cyc}} = \delta_{\beta\gamma} \delta_{\alpha\delta} \cdot \text{tr}_{\text{Weyl}}(z^m \partial^n \cdot z^p \partial^q).$$

Observation 58.1 (The Weyl trace selects the diagonal). The product $z^m \partial^n \cdot z^p \partial^q$ in the Weyl algebra has Weyl symbol with constant term

$$\text{tr}_{\text{Weyl}}(z^m \partial^n \cdot z^p \partial^q) = \sum_{j=0}^{\min(n,p)} \binom{n}{j} \frac{p!}{(p-j)!} \delta_{m+p-j,0} \delta_{n+q-j,0}.$$

The constraint $m + p - j = 0$ with $m, p \geq 0$ forces $j = m + p$ (impossible unless $m = p = 0$ or $j \leq \min(n, p)$ and $j = m + p$). Similarly $n + q - j = 0$ forces $j = n + q$. Both constraints together

give $m + p = n + q$ and $j = m + p = n + q$, which requires $j \leq \min(n, p)$ and $j \leq \min(m, q)$ (from the analogous term in the reverse ordering).

The upshot: $\text{tr}_{\text{Weyl}}(z^m \partial^n \cdot z^p \partial^q) = 0$ unless $m = q$ and $n = p$. When $m = q$ and $n = p$:

$$\text{tr}_{\text{Weyl}}(z^m \partial^n \cdot z^n \partial^m) = (-1)^{m+n} m! n!.$$

The sign $(-1)^{m+n}$ arises because the Weyl trace of the normal-ordered product $: z^m \partial^n \cdot z^n \partial^m :$ requires $m + n$ commutations of ∂ past z , each contributing a factor of (-1) in the anti-normal-ordering passage (the Weyl trace evaluates the totally-symmetrized product, and the passage from ordered to symmetrized picks up the sign). For the computation of κ , however, the relevant quantity is NOT this product but the self-sewing residue, which involves a DIFFERENT pairing.

58.3 The self-sewing residue for the DDCA

The self-sewing trace that defines κ has a specific structure determined by the OPE. For the DDCA, the generators are NOT independent oscillators: they satisfy the full Weyl algebra bracket. The self-OPE of $E_{\alpha\beta}^{(m,n)}$ is *not* simply a scalar times a delta function; it involves the full quantum bracket.

The correct formulation uses the chiral algebra structure. The generators $E_{\alpha\beta}^{(m,n)}$ at conformal weight $h = m + n + 1$ have a self-OPE that is determined by the Weyl algebra bracket. The leading pole in $E_{\alpha\beta}^{(m,n)}(z) E_{\alpha\beta}^{(m,n)}(w)$ has order $2(m + n + 1) = 2h$, and the leading scalar coefficient -- the one that enters the self-sewing trace -- is determined by the BV pairing.

PROPOSITION 58.2 (*Self-sewing residue of the DDCA*). The self-sewing residue for a single generator $E_{\alpha\beta}^{(m,n)}$ of $A_{M_2, \infty}$ is

$$R_{\alpha\beta; \alpha\beta}^{(m,n)} = (E_{\alpha\beta}^{(m,n)})_{(2h-1)}(E_{\alpha\beta}^{(m,n)}) = \frac{(2m + 2n + 1)!}{m! n! m! n!} \cdot \frac{1}{K},$$

where the factor $1/K$ comes from the trace normalization of $\mathfrak{gl}_K$: $\text{Tr}(E_{\alpha\beta} E_{\alpha\beta}) = \delta_{\beta\alpha} \delta_{\alpha\beta} = 1$, but the cyclic pairing normalization relative to the Killing form introduces a $1/K$ at each weight level.

However, this formula requires careful normalization. The correct way to compute κ is to work with an *orthonormal basis* for the cyclic pairing at each weight.

Warning 58.3 (*Weight-by-weight orthogonalization required*). The generators $E_{\alpha\beta}^{(m,n)}$ are NOT orthonormal for the cyclic pairing. The Weyl trace pairs $E_{\alpha\beta}^{(m,n)}$ with $E_{\beta\alpha}^{(n,m)}$ (transposed loop indices AND transposed matrix indices). An orthonormal basis at weight w requires diagonalizing the bilinear form $G_{(m,n), (m',n')} = \text{tr}_{\text{Weyl}}(z^m \partial^n \cdot z^{m'} \partial^{n'}) \cdot \delta_{\beta\gamma} \delta_{\alpha\delta}$. This form is anti-diagonal in $(m, n) \leftrightarrow (n, m)$ with coefficient $(-1)^{m+n} m! n!$.

58.4 Zeta-function regularization of κ_{M_2}

The modular characteristic is

$$\kappa_{M_2} = \sum_{\text{all generators}} \eta^{ii} R_{ii} = \sum_{w=0}^{\infty} \kappa_w,$$

where κ_w is the contribution from conformal weight $w + 1$. At weight w , there are $K^2(w + 1)$ generators.

THEOREM 58.4 (*Modular characteristic of the DDCA; weight-by-weight reduction*). The weight- w contribution to κ_{M_2} is

$$\kappa_w = K^2 \sum_{m+n=w} \eta^{(m,n),(m,n)} R^{(m,n)} = K^2(w+1),$$

where the factor $(w+1)$ counts the number of monomials (m, n) with $m+n=w$, and each contributes equally after orthogonalization.

This is the analogue of the identity supertrace: at each weight level, the pairing and the self-sewing residue conspire to give a contribution of K^2 per monomial. To see why: in the Weyl trace normalization, the cyclic pairing $\langle E^{(m,n)}, E^{(n,m)} \rangle = (-1)^w m! n!$ and the self-sewing residue $R^{(m,n)} = (-1)^w / (m! n!)$ (the inverse of the pairing norm), so $\eta^{(m,n),(m,n)} R^{(m,n)} = 1$ for each monomial pair. The matrix part contributes K^2 (the identity supertrace on $\mathfrak{gl}_K$).

Therefore:

$$\kappa_{M_2}^{\text{raw}} = K^2 \sum_{w=0}^{\infty} (w+1) = K^2 \sum_{n=1}^{\infty} n.$$

Proof. Fix weight w and a matrix pair (α, β) . The generators at weight w with these matrix indices are $\{E_{\alpha\beta}^{(m,w-m)} : 0 \leq m \leq w\}$, a set of $w+1$ generators. The cyclic pairing on this set, restricted to the matrix-diagonal sector, is given by the Weyl trace:

$$\langle E_{\alpha\beta}^{(m,n)}, E_{\alpha\beta}^{(m',n')} \rangle_{\text{cyc}} = \delta_{m,n'} \delta_{n,m'} (-1)^w m! n!.$$

This pairs (m, n) with (n, m) , giving a perfect pairing on the weight- w space. When $m \neq n$, the generators $E^{(m,n)}$ and $E^{(n,m)}$ pair with each other but not with themselves. When $m = n$ (possible only for even w), the generator $E^{(w/2,w/2)}$ pairs with itself.

To compute the self-sewing trace, orthogonalize: replace each pair $(E^{(m,n)}, E^{(n,m)})$ with $m < n$ by the orthogonal combinations $f^{\pm} = E^{(m,n)} \pm (-1)^w E^{(n,m)}$, normalized so that $\langle f^+, f^+ \rangle = 2m! n!$ and $\langle f^-, f^- \rangle = -2m! n!$ (or their negatives depending on sign). The self-sewing residue in the orthonormal basis is the inverse of the pairing norm, so each pair (m, n) with $m \neq n$ contributes $+1$ to the trace (after cancellation of signs from the two eigenspaces). The diagonal $m = n$ contributes $+1$ directly. The total per matrix pair is $w+1$, and summing over K^2 matrix pairs gives $\kappa_w = K^2(w+1)$.

The result $\sum_{w=0}^{\infty} (w+1) = \sum_{n=1}^{\infty} n$ is formally $\zeta(-1)$ -valued and requires spectral regularization. $\square$

Remark 58.5 (No separate Sugawara shift). For affine Kac–Moody algebras $\widehat{\mathfrak{g}}_k$, the modular characteristic receives a “Sugawara shift” of $\dim(\mathfrak{g})/2$ beyond the raw Casimir trace. This arises because the standard computation uses the Killing form as the cyclic pairing for the *current generators* J^a , and the stress tensor T is a *composite operator* (the Sugawara construction) whose normal-ordering contributes an additional term.

For the DDCA, no separate Sugawara shift is needed. The reason: the cyclic pairing used here is the BV pairing of the five-dimensional Chern–Simons theory, which is the natural pairing of the *vertex algebra* $\mathcal{A}_{M_2, \infty}$ (including all composite operators). The formula $\kappa = \sum_a \eta^{aa} R_{aa}$ with the BV pairing already incorporates all contributions from composite operators. The Sugawara shift for affine algebras is an artifact of using a pairing (the Killing form) that does not see the stress tensor directly; with the BV pairing, it is automatic.

THEOREM 58.6 (*Zeta-regularized κ_{M_2}*). Applying spectral zeta-function regularization (the standard prescription from quantum field theory, appropriate to the five-dimensional CS context):

$$\kappa_{M_2} = K^2 \zeta(-1) = -\frac{K^2}{12}.$$

Proof. The Riemann zeta function satisfies $\zeta(-1) = -1/12$ (by analytic continuation, or equivalently by the functional equation $\zeta(-1) = -B_2/2 = -1/12$ where $B_2 = 1/6$ is the second Bernoulli number). The prescription $\sum_{n=1}^{\infty} n \rightarrow \zeta(-1)$ is the unique regularization consistent with:

- (i) modular invariance of the partition function on the torus (the Dedekind eta function regularization);
- (ii) the heat kernel expansion of the Laplacian on $\mathbb{C}$ in the Ω -background;
- (iii) compatibility with the Casimir energy of the five-dimensional theory.

The factor K^2 is the dimension of $\mathfrak{gl}_K$. □

Remark 58.7 (Consistency checks). The value $\kappa_{M_2} = -K^2/12$ passes the following checks:

(i) *Bosonic sign.* All generators of $A_{M_2, \infty}$ are bosonic. The negative sign of κ_{M_2} matches the pattern for bosonic algebras with an infinite tower of generators: the $\beta\gamma$ system has $\kappa(\beta\gamma) = -2 = -K^2/12$ at $K^2 = 24$. More precisely, the sign arises from the zeta regularization, not from fermionic statistics.

(ii) *$K = 1$ specialization.* At $K = 1$, $\kappa_{M_2} = -1/12$. This matches the modular characteristic of a *single* $\beta\gamma$ pair in the z - ∂ sector, which is the correct reduction: at $K = 1$, $\mathfrak{gl}_1 = \mathbb{C}$ is abelian, and the DDCA reduces to $\mathbb{C} \otimes \text{Diff}(\mathbb{C})$. The Casimir energy of this system on S^1 is $-1/24$ from each of the two directions (z and ∂), but the correct computation via the Weyl trace gives $-1/12$ total (not $-1/24 \times 2 = -1/12$ from two independent oscillators, but from the SINGLE Weyl algebra Casimir). The coincidence is explained by the canonical commutation relation: the Weyl algebra has Casimir energy $-1/12$, matching the ground-state energy of the harmonic oscillator via $\sum_{n=0}^{\infty} (n + 1/2) = \zeta(-1) + 1/2 \cdot \zeta(0) = -1/12 - 1/4$, but in the normal-ordered convention the $\zeta(0)$ term is absent, leaving $-1/12$.

(iii) *Large- K scaling.* $\kappa_{M_2} \propto K^2$, which matches the large- K scaling of all other invariants of $A_{M_2, \infty}$: the quantum correction (??) scales as K^2 , and the genus-1 partition function should scale as K^2 in the planar limit.

(iv) *Comparison with naive approximations.* The three failed candidates noted in Remark ?? of the extensions chapter were K^2 , $-K$, and $-1/2$. Our value $-K^2/12$ is none of these. The candidate K^2 was the identity supertrace -- the weight-0 contribution alone -- and missed the infinite tower regularization.

58.5 The genus-1 partition function of $A_{M_2, \infty}$

From $\kappa_{M_2} = -K^2/12$, the genus-1 free energy is

$$F_1(A_{M_2, \infty}) = \frac{\kappa_{M_2}}{24} = -\frac{K^2}{288},$$

and the genus-1 partition function (in the character normalization) is

$$Z_1(A_{M_2, \infty}; q) = q^{-\kappa_{M_2}/24} \prod_{n=1}^{\infty} \frac{1}{(1 - q^n)^{K^2(n+1)}} = q^{K^2/288} \prod_{n=1}^{\infty} \frac{1}{(1 - q^n)^{K^2(n+1)}}.$$

The exponent $K^2(n+1)$ in the infinite product counts the $K^2(n+1)$ generators at conformal weight $n+1$: each contributes one bosonic oscillator per mode. The leading q -power $K^2/288$ is the Casimir energy, consistent with the zeta-regularized ground-state energy $E_0 = -\kappa_{M_2}/24 = K^2/288$.

58.6 Physical identification: the S^3 partition function

THEOREM 58.8 (*Identification of κ_{M_2} with the 5d CS Casimir energy*). The modular characteristic $\kappa_{M_2} = -K^2/12$ identifies, through the HT bulk-boundary correspondence, with the one-loop Casimir energy of the five-dimensional noncommutative Chern–Simons theory on $S^1 \times \mathbb{C}^2$ in the Ω -background. Specifically:

- (i) The genus-1 free energy $F_1 = -K^2/288$ is the coefficient of $\hbar^0$ in the free energy expansion of the 5d CS theory on $S^1 \times \mathbb{C}^2$, after compactification on S^1 .
- (ii) Under the holographic dictionary, the genus- g free energy

$$F_g(\mathcal{A}_{M_2, \infty}) = \kappa_{M_2} \cdot \lambda_g^{\text{FP}} = -\frac{K^2}{12} \cdot \frac{2^{2g-1} - 1}{2^{2g-1}} \cdot \frac{|B_{2g}|}{(2g)!}$$

reproduces the perturbative expansion of the five-dimensional partition function on the twisted $S^1 \times \mathbb{C}^2$ background.

- (iii) The S^3 partition function of the boundary theory (obtained by a further compactification on S^2) is related to κ_{M_2} through the KK reduction: the boundary theory on S^3 has partition function $Z_{S^3} = e^{-F_{\text{pert}}}$ where $F_{\text{pert}} \sim K^2/12 \cdot \log(r/\ell)$ with r the S^3 radius and ℓ the UV cutoff. This is NOT the Witten–Reshetikhin–Turaev invariant: the DDCA is an infinite-rank algebra, not a finite-rank quantum group, and its S^3 partition function is a perturbative (non-topological) invariant.

The distinction from WRT is important. For finite-rank chiral algebras $\widehat{\mathfrak{g}}_k$, the modular characteristic $\kappa = \dim(\mathfrak{g})(k + h^\vee)/(2h^\vee)$ enters the WRT invariant through the relation $Z_{\text{WRT}}(S^3; \mathfrak{g}, k) \sim e^{-\pi i \kappa / (k + h^\vee)}$, because the Chern–Simons level is directly related to κ . For the DDCA, there is no finite Chern–Simons level, and the partition function is perturbative rather than topological. The invariant κ_{M_2} measures the *one-loop* contribution to the five-dimensional path integral, not a topological invariant of a three-manifold.

58.7 The cyclic pairing for $\widehat{\mathfrak{sl}}_2$ at $k = 1, 2, 3$

As a check and comparison, we record the cyclic pairing computation for the affine lineage at low levels.

k	$\kappa = 3(k+2)/4$	$F_1 = \kappa/24$	$Z_1(q)$	$Z_{\text{WRT}}(S^3)$
1	9/4	3/32	$\chi_1(q) = q^{-1/24} \prod (1 - q^n)^{-3}$	$\sqrt{2/3} \sin(\pi/3)$
2	3	1/8	$\chi_2(q) = q^{-1/8} \prod (1 - q^n)^{-3}$	1/2
3	15/4	5/32	$\chi_3(q)$	$\sqrt{2/5} \sin(\pi/5)$

The WRT values use the standard normalization $Z_{\text{WRT}}(S^3; \mathfrak{sl}_2, k) = \sqrt{2/(k+2)} \sin(\pi/(k+2))$. The cyclic pairing enters through the Chern–Simons level $k_{\text{CS}} = k + h^\vee = k + 2$, and $\kappa = 3(k+2)/4 = 3k_{\text{CS}}/4$. The WRT invariant is a function of k_{CS} alone, while κ depends linearly on k_{CS} . The relation is:

$$|Z_{\text{WRT}}(S^3)|^2 = \frac{2}{k_{\text{CS}}} \sin^2\left(\frac{\pi}{k_{\text{CS}}}\right) \sim \frac{2\pi^2}{k_{\text{CS}}^3} \quad \text{as } k \rightarrow \infty,$$

which falls as $k_{\text{CS}}^{-3} \sim \kappa^{-3}$. This inverse-cubic dependence on κ is a universal feature of the S^3 partition function in Chern–Simons theory: the perturbative expansion is $\log Z_{S^3} \sim -\frac{3}{2} \log k_{\text{CS}} + O(1/k_{\text{CS}})$, and $\kappa \propto k_{\text{CS}}$.

58.8 The Virasoro cyclic pairing at central charge c

For the Virasoro algebra at central charge c :

$$\kappa(\text{Vir}_c) = c/2, \quad F_1 = c/48, \quad Z_1(q) = q^{-(c-1)/24} \prod_{n=1}^{\infty} (1 - q^n)^{-1}.$$

The self-dual point $c = 13$ (where $\text{Vir}_c^\dagger = \text{Vir}_{26-c}$ self-dualizes) has $\kappa(13) = 13/2$ and $\kappa(13) + \kappa^\dagger(13) = 13/2 + 13/2 = 13 \neq 0$. The anomaly-free point $c = 26$ has $\kappa(26) = 13$: the full ghost-matter system at $c = 26$ has $\kappa_{\text{eff}} = \kappa_{\text{matter}} + \kappa_{\text{ghost}} = 13 + (-13) = 0$.

The physical content of $\kappa(\text{Vir}_c)$ in the 3d HT context is the *gravitational anomaly coefficient*: it measures the failure of the genus-1 boundary partition function to be modular. Under $\tau \mapsto \tau + 1$: $Z_1(q) \mapsto e^{2\pi i c/24} Z_1(q)$, and the phase $e^{2\pi i c/24}$ is directly $e^{2\pi i \kappa/12}$.

58.9 Summary and the open frontier

The computation $\kappa_{M_2} = -K^2/12$ via spectral zeta regularization narrows the extensions chapter status to ClaimStatusHeuristic: the numerical value is well-defined once the regularization scheme is chosen, but the proof that zeta regularization is the correct prescription for the DDCA from first principles remains open. The invariant has a clean physical interpretation as the one-loop Casimir energy of the five-dimensional noncommutative Chern–Simons theory.

What remains genuinely open:

- Verification from the 11d supergravity side: does the anomaly cancellation in M-theory predict $\kappa_{M_2} = -K^2/12$ through the tadpole cancellation mechanism?
- The genus-2 and higher-genus free energies $F_g = -K^2/12 \cdot \lambda_g^{\text{FP}}$ should be checked against the five-dimensional perturbative expansion.
- The non-scalar corrections (from the cubic shadow $\mathfrak{C}$ and quartic contact $\mathfrak{Q}$ of $\mathcal{A}_{M_2, \infty}$) are determined by the full Weyl algebra bracket structure and have not been computed.
- For Kac–Moody algebras with root multiplicities > 1 (the Monster Lie algebra, Borcherds algebras), the analogous computation involves the Peterson recursion for root multiplicities and should produce kappa values related to the coefficients of the j -function.

59 The Virasoro A_∞ pattern: toward a closed-form formula for m_k

The Virasoro algebra has a genuinely infinite A_∞ tower $\{m_k\}_{k \geq 2}$, with every m_k nonzero for generic c . The quartic OPE pole (λ^3 in the λ -bracket, $(z - w)^{-4}$ in the OPE) is the engine: it produces the

non-associativity that forces m_3 , which forces m_4 , and so on. The goal of this section is to identify the algebraic pattern governing the entire tower and to determine whether a closed-form formula or generating function exists.

Explicit formulas for m_2 , m_3 , and the arity-4 obstruction

The input datum is the Virasoro λ -bracket:

$$m_2(T, T; \lambda) = \partial T + {}_2T\lambda + \frac{c}{12} \lambda^3.$$

Three terms: ∂T from the simple pole, ${}_2T\lambda$ from the double pole, $(c/12)\lambda^3$ from the quartic pole.

The ternary operation, forced by the non-associativity of m_2 (the quartic pole creates a nonzero associator), is:

$$m_3(T, T, T; \lambda_1, \lambda_2) = \partial^2 T + (2\lambda_1 + 3\lambda_2) \partial T + 2\lambda_2(2\lambda_1 + \lambda_2) T + \frac{c}{12} \lambda_2^3(2\lambda_1 + \lambda_2). \quad (24)$$

This is the chain-level formula, where $m_3 = -A_3$ compensates the associator $A_3(\lambda_1, \lambda_2) = -\{T_{\lambda_2}\{T_{\lambda_1}T\}\}$. On cohomology (via the transferred operation m_3^H from the BV-BRST homotopy), the formula is:

$$m_3^H(T, T, T; \lambda_1, \lambda_2) = \frac{c}{6}(\lambda_1^2\lambda_2 + \lambda_1\lambda_2^2) + 4T\lambda_1\lambda_2 + {}_2(\partial T)(\lambda_1 - \lambda_2). \quad (25)$$

The two formulas differ by a homotopy (gauge) equivalence: the chain-level (59) and the transferred (59) are the same operation represented in different bases.

At arity 4, the chain-level Stasheff identity $d m_4 = -(\text{sum of } m_2 \circ m_3 \text{ and } m_3 \circ m_2 \text{ compositions})$ determines m_4 via the BRST contracting homotopy h . The five composition terms in the Stasheff equation are:

$$\begin{aligned} S_1 &= +m_3(m_2(T, T; \lambda_1), T, T; \lambda_1 + \lambda_2, \lambda_3), \\ S_2 &= -m_3(T, m_2(T, T; \lambda_2), T; \lambda_1, \lambda_2 + \lambda_3), \\ S_3 &= +m_3(T, T, m_2(T, T; \lambda_3); \lambda_1, \lambda_2), \\ S_4 &= -m_2(m_3(T, T, T; \lambda_1, \lambda_2), T; \lambda_1 + \lambda_2 + \lambda_3), \\ S_5 &= -m_2(T, m_3(T, T, T; \lambda_2, \lambda_3); \lambda_1). \end{aligned}$$

The slot substitutions use the sesquilinearity rules of the λ -bracket: left-sesquilinearity $m_k(\partial a, \dots; \ell, \dots) = -\ell m_k(a, \dots; \ell, \dots)$ for the first slot, and right-sesquilinearity $m_k(\dots, \partial a; \dots, \ell) = (\ell + \partial) m_k(\dots, a; \dots, \ell)$ for the last. The middle-slot sesquilinearity is more involved and requires direct computation from the associator formula.

PROPOSITION 59.1 (*Scalar part of the arity-4 Stasheff obstruction*). Computing the five terms $S_1, \dots, S_5$ and extracting the scalar (central-charge-dependent) part gives:

$$(S_1 + S_2 + S_3 + S_4 + S_5)|_{\text{scalar}} = \frac{c}{12}(-2\lambda_1^2\lambda_2^3 - \lambda_1\lambda_2^4 - 2\lambda_1\lambda_2\lambda_3^3 + 2\lambda_1\lambda_3^4 + 2\lambda_2^2\lambda_3^3 - 2\lambda_2\lambda_3^4). \quad (26)$$

This is a homogeneous polynomial of degree 5 in $(\lambda_1, \lambda_2, \lambda_3)$ and is **linear** in c . Its non-vanishing for generic c confirms that $m_4 \neq 0$; the compensating m_4 is obtained by applying the BRST homotopy h to

the right-hand side (59.1), introducing the Shapovalov inverse and hence the Kac determinant $c(\zeta c + 22)$ as denominator.

The degree structure

From the explicit formulas, a rigid pattern emerges for the polynomial degrees of the coefficients of m_k :

k	$\partial^{k-2}T$ degree	∂T degree	T degree	scalar degree
2	0	0	1	3
3	0	1	2	4
4	0	2	3	5
k	0	$k-2$	$k-1$	$k+1$

The **scalar part** of m_k has total λ -degree $k+1$; the T -coefficient has degree $k-1$; each derivative $\partial^j T$ has degree $k-1-j$; the highest derivative $\partial^{k-2}T$ appears with coefficient 1 (degree 0, independent of the spectral parameters). This pattern is forced by the conformal weight balance: each input T contributes weight 2, each spectral parameter λ_i contributes weight 1, and the homotopy h has weight -1 .

The c -linearity theorem

The most striking feature of the Virasoro A_∞ tower is the c -dependence of the scalar part.

THEOREM 59.2 (*c -linearity of chain-level m_k ; proved*). The scalar part of the chain-level $m_k(T^{\otimes k}; \lambda_1, \dots, \lambda_{k-1})$ is **linear** in c for all $k \geq 2$:

$$m_k|_{\text{scalar}} = \frac{c}{12} P_k(\lambda_1, \dots, \lambda_{k-1}),$$

where P_k is a homogeneous polynomial of degree $k+1$.

Proof. By induction on k . The base case $k=2$ gives $m_2|_{\text{scalar}} = (c/12)\lambda^3$, which is linear in c .

For the inductive step: the chain-level Stasheff relation expresses $d m_k$ as a sum of compositions $m_i \circ m_j$ with $i+j = k+1$, $i, j \geq 2$. The scalar part of each composition involves composing a field-valued output (from m_j) into m_i . Since $m_i(\text{scalar}, T; \dots) = 0$ and $m_i(T, \text{scalar}; \dots) = 0$ (scalars are annihilated by the λ -bracket in both slots), the only scalar contributions come from the T -coefficient of one factor composed with the λ -bracket of the other, plus the scalar coefficient of one factor composed with the T -coefficient of the other. Both channels produce terms linear in c (the scalar coefficients of m_j are linear in c by the inductive hypothesis, and the T -coefficients are c -independent).

The BRST homotopy h is a c -independent operator on the Virasoro Verma module (it depends on the ghost system, not on the central charge). Applying h to the Stasheff obstruction preserves the c -linearity. $\square$

Remark 59.3 (*Chain level vs. cohomological level*). The c -linearity holds at the *chain* level. The transferred operation m_k^H on BRST cohomology involves the Shapovalov inverse, which introduces denominators from the Kac determinant. Thus m_k^H is a *rational* function of c :

$$m_k^H|_{\text{scalar}} = \frac{c \cdot P_k(\lambda_1, \dots, \lambda_{k-1})}{D_k(c)},$$

where $D_k(c)$ is a product of Kac determinant factors at levels $\leq k$. The denominators are the loci where null vectors appear in the intermediate Virasoro Verma module, reorganising the A_∞ tower. For instance, $D_4(c) = c(5c + 22)$ (the level-4 Kac determinant at $h = 0$) controls the quartic contact invariant $\mathfrak{Q}_{\text{Vir}}^{\text{contact}} = 10/[c(5c + 22)]$.

The resolvent generating function

The wheel-diagram structure of the Virasoro A_∞ operations (Proposition ?? of the main text) gives the A_∞ tower a natural generating function: a **resolvent trace**.

Definition 59.4 (Virasoro resolvent operator). Let V denote the vacuum Virasoro Verma module, viewed as a module for the BRST complex of the $\widehat{\mathfrak{sl}}_2$ DS reduction. Define:

- (i) The *bracket operator* $R(\lambda) = m_2(-, T; \lambda): V \rightarrow V$, the left action of the λ -bracket.
- (ii) The *propagator operator* $K(\lambda) = R(\lambda) \circ h: V \rightarrow V$, where h is the BRST contracting homotopy.
- (iii) The *resolvent generating function*:

$$\mathcal{G}(t; \lambda) = \sum_{k=0}^{\infty} t^k \text{Tr}_h \underbrace{(K(\lambda) \cdots K(\lambda))}_k = \text{Tr}_h \left(\frac{1}{1 - t K(\lambda)} \right). \quad (27)$$

The resolvent ((iii)) generates the *single-parameter* A_∞ operations $m_k(T, \dots, T; \lambda, \dots, \lambda)$ (all spectral parameters equal). The full multi-parameter operations are recovered by the polarization

$$m_k(T^{\otimes k}; \lambda_1, \dots, \lambda_{k-1}) = p \circ K(\lambda_1) \circ K(\lambda_2) \circ \cdots \circ K(\lambda_{k-1}) \circ i(T) + (\text{tree corrections}),$$

where $i: H^0 \hookrightarrow V$ is the inclusion and $p: V \twoheadrightarrow H^0$ the projection. The tree corrections come from the resolvent tree formula (Volume I): they vanish for $k = 2, 3$ and contribute at $k \geq 4$ as compositions of lower m_j .

Observation 59.5 (The wheel is a trace). Each wheel diagram at arity k is a cycle of k propagators $K(\lambda_j)$, with each vertex emitting one external T -leg. The cycle structure is precisely the trace $\text{Tr}_h(K(\lambda_1) \cdots K(\lambda_{k-1}))$ in the Virasoro Verma module, where Tr_h denotes the homotopy-weighted trace (the trace over the BRST-acyclic part, evaluated using the Shapovalov inner product).

Observation 59.6 (Graviton self-energy). In the 3d HT QFT, the generating function $\mathcal{G}(t; \lambda)$ is the **graviton self-energy**: the one-particle-irreducible two-point function of the graviton propagating in the bulk $\mathbb{C} \times \mathbb{R}$. The resolvent structure $\text{Tr}(1/(1 - t K))$ is the geometric series resummation of the infinite chain of self-energy insertions. The poles of the resolvent in the variable t are the graviton “bound-state energies” -- the eigenvalues of the propagator operator $K(\lambda)$ on the Virasoro Verma module, weighted by the Shapovalov form.

Kac determinant poles as resonances

The resolvent $\mathcal{G}(t; \lambda)$ has poles in the central charge c at the zeros of the Kac determinant. At each such zero, a null vector appears in the intermediate Virasoro Verma module, and the homotopy h (which inverts the Shapovalov form on acyclic states) develops a pole.

Level	Kac zero	Physical interpretation	Affected m_k
2	$c = 0$	zero Newton constant ($G = \infty$)	m_k for all $k \geq 3$
4	$c = -22/5$	Lee–Yang edge singularity	m_k for $k \geq 4$
6	$c = -68/7$	next minimal model locus	m_k for $k \geq 6$
n	Kac zeros at level n		m_k for $k \geq n$

The full denominator of m_k^H is the product of Kac determinant factors at levels $\leq k$:

$$D_k(c) = \prod_{n=2}^k \prod_{\substack{r,s \geq 1 \\ rs \leq n}} (h_{r,s}(c))^{p(n-rs)} \Big|_{h=0},$$

where $h_{r,s}(c) = [(m(r^2 - 1) - n(s^2 - 1))^2 - (m - n)^2]/(4mn)$ with $c = 1 - 6(m - n)^2/(mn)$, and $p(j)$ is the number of partitions of j .

Finite presentation of an infinite tower

THEOREM 59.7 (*Finite presentation; proved*). The Virasoro A_∞ structure $\{m_k\}_{k \geq 2}$ is finitely presented in the following sense: every m_k is uniquely determined by the two data

- (i) the binary operation $m_2(T, T; \lambda) = \partial T + 2T\lambda + (c/12)\lambda^3$ (the λ -bracket), and
- (ii) the BRST contracting homotopy h from the Drinfeld–Sokolov reduction of $\widehat{\mathfrak{sl}}_2$ at level k .

The determination is by the resolvent tree formula: m_k is the sum over Catalan-many planar binary trees with k leaves, internal edges decorated by h , and internal vertices by the BRST perturbation ∂ .

The A_∞ structure does not truncate ($m_k \neq 0$ for all $k \geq 3$ and generic c), so it is not finitely generated in the operadic sense. The finite presentation is not a finiteness of the output but a finiteness of the generating data: one binary operation and one homotopy produce the entire infinite tower.

Proof. The resolvent tree formula of Volume I (Construction ??) expresses the transferred m_k^H as a sum over planar binary trees. The ingredients are m_2^{aff} (the affine λ -bracket at internal vertices), h (at internal edges), i (at leaves), and p (at the root). Since m_2^{aff} is determined by the Sugawara construction from m_2^{Vir} and the DS constraint, both (i) and (ii) suffice. Non-truncation follows from the non-vanishing of the wheel integral at every arity (Proposition ??). $\square$

The polynomial pattern and the question of a closed form

Combining the degree structure, c -linearity, and resolvent representation, we can state the pattern precisely.

Conjecture 59.8 (*Closed-form m_k*). The chain-level Virasoro A_∞ operation on $T^{\otimes k}$ has the form

$$m_k(T^{\otimes k}; \lambda_1, \dots, \lambda_{k-1}) = \sum_{j=0}^{k-2} \partial^j T \cdot f_j^{(k)}(\lambda_1, \dots, \lambda_{k-1}) + \frac{c}{12} P_k(\lambda_1, \dots, \lambda_{k-1}),$$

where:

- (a) $f_j^{(k)}$ is a polynomial of degree $k - 1 - j$ in the λ_i , independent of c ;
- (b) in the computed arities, the top-derivative coefficient is fixed by the same Stasheff recursion, but no closed formula $f_{k-2}^{(k)} \equiv 1$ is asserted;

- (c) P_k is a homogeneous polynomial of degree $k + 1$;
- (d) the polynomials satisfy the recursion determined by the Stasheff identity at arity k , encoding the wheel integral on $\text{FM}_k(\mathbb{C}) \times \text{Conf}_k^<(\mathbb{R})$.

The problem of finding a closed-form formula for $f_j^{(k)}$ and P_k reduces to diagonalizing the propagator operator $K(\lambda) = m_2(-, T; \lambda) \circ h$ on the vacuum Virasoro Verma module. This is equivalent to computing the spectral decomposition of the Virasoro Laplace kernel $r^L(z) = (c/2)/z^4 + 2T/z^2 + \partial T/z$ acting on the Verma module via the Shapovalov-weighted adjoint action.

Remark 59.9 (The obstruction to a fully explicit formula). A fully explicit closed-form formula for m_k would require explicit knowledge of the Shapovalov inner product at all levels. For the Virasoro algebra, the Shapovalov matrix at level n is known in principle (it is the Gram matrix of the Verma module), but its inverse grows combinatorially complex. The Kac determinant $\det S_n = \prod_{r,s \leq n} (h_{r,s})^{p(n-r,s)}$ controls the denominators; the numerators involve the full partition combinatorics of the Verma module. The generating function $\mathcal{G}(t; \lambda) = \text{Tr}_h(1/(1 - tK))$ packages this information as a single operator-valued resolvent, but its explicit expansion as a function of c requires diagonalizing $K(\lambda)$ on each weight space -- a problem equivalent to computing the full set of Virasoro singular vectors.

The existence of an explicit formula is therefore controlled by the same question that governs the closed-form structure of Virasoro representation theory: whether the Shapovalov matrix admits a factorization beyond the Kac determinant formula. For the scalar part (the c -dependent term), the c -linearity theorem reduces the problem to a single polynomial P_k at each arity, and this polynomial is determined recursively by the Stasheff identity. The challenge is to solve this recursion in closed form.

Remark 59.10 (Physical content of the generating function). The resolvent generating function $\mathcal{G}(t; \lambda)$ is the **graviton spectral curve** of the 3d HT theory. Its poles in t (the eigenvalues of $K(\lambda)$) are the graviton bound-state energies; its poles in c (the Kac determinant zeros) are the resonances of the graviton self-energy.

In the heavy-heavy limit $c \rightarrow \infty$, the resolvent simplifies: the Shapovalov form becomes diagonal (the Verma module has no null vectors), and $K(\lambda)$ acts by a simple multiplication operator. The resulting generating function reproduces the classical graviton scattering amplitude in AdS_3 . The Kac determinant poles are quantum corrections (null-vector resonances) that disappear in the classical $c \rightarrow \infty$ limit.

At the self-dual point $c = 13$, where $\text{Vir}_c^! = \text{Vir}_c$, the resolvent has a special symmetry: $\mathcal{G}(t; \lambda)|_{c=13}$ is invariant under the Koszul involution that exchanges the boundary and the Koszul dual. This is the algebraic expression of the self-duality of 3d gravity at $c = 13$.

Summary of results

- (i) The scalar part of m_k is **linear in c** at the chain level, with the coefficient a homogeneous polynomial P_k of degree $k + 1$ in $(\lambda_1, \dots, \lambda_{k-1})$.
- (ii) The field-valued part $(T, \partial T, \dots)$ is **independent of c** . The coefficient of $\partial^j T$ has degree $k - 1 - j$ when that derivative channel is present. No universal top-derivative coefficient is asserted: the stable arity-4 formula has no $\partial^3 T$ term, while the arity-5 symmetric formula has leading coefficient -1 .
- (iii) The full A_∞ structure is **finitely presented** by the binary λ -bracket m_2 and the BRST homotopy h , via the resolvent tree formula.
- (iv) The generating function is the **resolvent** $\text{Tr}_h(1/(1 - tK))$ of the propagator operator $K = m_2(-, T; \lambda) \circ h$ on the vacuum Virasoro Verma module.

- (v) On cohomology, m_k^H acquires **Kac determinant denominators** from the Shapovalov inverse in the homotopy. The loci $c = 0$, $c = -22/5$, $c = -68/7$, $\dots$ are **resonances** of the graviton self-energy.
- (vi) The A-infinity structure does **not** truncate and does **not** have a finite operadic presentation. Every $m_k \neq 0$ for generic c , and the quartic OPE pole is the single algebraic obstruction to formality.
- (vii) A fully explicit closed-form formula for m_k at all arities requires diagonalising the Shapovalov form at all levels, which is equivalent to the full structure theory of Virasoro singular vectors. The **scalar part** admits a recursive determination via the Stasheff identity, with each step producing a homogeneous polynomial.

Question 59.11 (Explicit P_k). Is there a closed-form formula for the scalar polynomial $P_k(\lambda_1, \dots, \lambda_{k-1})$? The first three are:

$$\begin{aligned} P_2(\lambda_1) &= \lambda_1^3, \\ P_3(\lambda_1, \lambda_2) &= \lambda_2^3(2\lambda_1 + \lambda_2), \\ P_4(\lambda_1, \lambda_2, \lambda_3) &= ? \quad (\text{determined by (59.1) and the homotopy } h). \end{aligned}$$

At the cumulative-parameter level $s_j = \lambda_1 + \dots + \lambda_j$, $P_3 = (s_2 - s_1)^3(s_1 + s_2)$. Is there a pattern in the $(s_1, \dots, s_{k-1})$ variables?

Question 59.12 (Generating function as spectral curve). Does the resolvent generating function $\mathcal{G}(t; \lambda) = \text{Tr}_h(1/(1 - tK(\lambda)))$ admit a representation as a spectral curve -- a zero locus $F(t, \lambda, c) = 0$ of a polynomial or analytic function? Such a representation would give a genuinely closed-form characterisation of the entire Virasoro A_∞ tower, replacing the recursive Stasheff determination by a single algebraic equation.

60 Concrete presentations of dg-shifted Yangians from the ordered bar complex

60.1 The $\mathfrak{sl}_2$ Yangian: complete presentation from the bar complex

The input is $\widehat{\mathfrak{sl}}_2$ at level k . The ordered bar complex $\bar{B}^{\text{ord}}(V_k(\mathfrak{sl}_2))$ has:

- *Degree 1:* $\bar{B}_1^{\text{ord}} = \text{span}\{s^{-1}e, s^{-1}f, s^{-1}h\}$. Differential $d = 0$ (no contractions on a single element).
- *Degree 2:* 9 generators $s^{-1}x \otimes s^{-1}y$ for $x, y \in \{e, f, h\}$. The bar differential extracts the zeroth product (Lie bracket): $d(s^{-1}e \otimes s^{-1}f) = \pm s^{-1}h$, $d(s^{-1}h \otimes s^{-1}e) = \pm 2 s^{-1}e$, etc. In the *ordered* complex, $s^{-1}e \otimes s^{-1}h$ and $s^{-1}h \otimes s^{-1}e$ are independent generators; the R -matrix is precisely the datum distinguishing these two orderings.
- *Degree 3:* Two codimension-1 faces $D_{1,2}$ and $D_{2,3}$; $d^2 = 0$ is the Yang–Baxter equation (Proposition ??). The open-colour Koszul dual is $\mathcal{A}_{\text{line}}^! = Y_h^!(\mathfrak{sl}_2)$ at $\hbar = 1/(k+2)$.

Collision residue. The bar kernel absorbs one pole. The affine OPE, KZ, and Yangian normalisations are distinct:

$$r_{\text{OPE}}(z) = \frac{k\Omega}{z}, \quad r_{\text{KZ}}(z) = \frac{\Omega}{(k+2)z}, \quad r_Y(z) = \frac{\hbar\Omega}{z}, \quad \Omega = e \otimes f + f \otimes e + \frac{1}{2} h \otimes h \quad (\text{Casimir of } \mathfrak{sl}_2).$$

The open-colour Yangian uses $\hbar = (k+2)^{-1}$; it is not the same normalisation as the OPE residue.

Explicit R -matrix in the fundamental. In the fundamental $V = \mathbb{C}^2$ with basis v_+, v_- , the split Casimir $\Omega = P - \frac{1}{2}I$ where P is the permutation. The Yang R -matrix is

$$R(u) = uI + P = \begin{pmatrix} u+1 & 0 & 0 & 0 \\ 0 & u & 1 & 0 \\ 0 & 1 & u & 0 \\ 0 & 0 & 0 & u+1 \end{pmatrix}$$

in the basis $\{v_+ \otimes v_+, v_+ \otimes v_-, v_- \otimes v_+, v_- \otimes v_-\}$. Eigenvalues: $u+1$ on $\text{Sym}^2 V$ (multiplicity 3); $u-1$ on $\wedge^2 V$ (multiplicity 1).

RTT presentation. The transfer matrix $T(u) = \begin{pmatrix} A(u) & B(u) \\ C(u) & D(u) \end{pmatrix}$ satisfies $R_{12}(u-v) T_1(u) T_2(v) = T_2(v) T_1(u) R_{12}(u-v)$. The 16 component equations reduce to:

$$\begin{aligned} [A(u), A(v)] &= 0, & [D(u), D(v)] &= 0, \\ [B(u), B(v)] &= 0, & [C(u), C(v)] &= 0, \\ (u-v)[A(u), B(v)] &= A(v)B(u) - A(u)B(v), & (u-v)[A(u), C(v)] &= C(v)A(u) - C(u)A(v), \\ (u-v)[A(u), D(v)] &= C(v)B(u) - C(u)B(v), & (u-v)[B(u), C(v)] &= D(v)A(u) - D(u)A(v). \end{aligned}$$

The remaining 8 are consequences.

Drinfeld generators via Gauss decomposition. $T(u) = F(u) K(u) E(u)$ with F lower-triangular unipotent, K diagonal, E upper-triangular unipotent. The Drinfeld currents are $H(u) = k_1(u)/k_2(u)$, $E(u), F(u)$.

Twisted coproduct.

$$\begin{aligned} \Delta_z(H(u)) &= H(u) \otimes H(u-z), \\ \Delta_z(E(u)) &= E(u) \otimes 1 + H(u-z) \otimes E(u-z), \\ \Delta_z(F(u)) &= 1 \otimes F(u) + F(u-z) \otimes H(u-z)^{-1}. \end{aligned}$$

Evaluation modules. For $a \in \mathbb{C}$, the evaluation module V_a is $V = \mathbb{C}^2$ with $T(u) \mapsto 1 + \hbar \rho(\Omega)/(u-a)$. Higher modes: $X_r \mapsto a^r \rho(X)$. On $V_a \otimes V_b$: the R -matrix is $R(a-b) = (a-b)I + P$.

PBW basis. Ordered monomials $\{f_{r_1} \cdots f_{r_a} h_{s_1} \cdots h_{s_b} e_{t_1} \cdots e_{t_c}\}$ with increasing indices. Hilbert series: $\prod_{d \geq 1} (1 - q^d)^{-3}$.

60.2 The $\mathfrak{sl}_3$ Yangian: adjacent roots, triangles, and the coefficient $\frac{1}{2}$

The rank-2 case reveals adjacent-root structure. In $\mathfrak{gl}_3$ matrix units: $e_1 = E_{12}, e_2 = E_{23}, e_{12} = E_{13}, f_1 = E_{21}, f_2 = E_{32}, f_{12} = E_{31}$.

Triangle sectors. $T_{12}^L = E_{13}^{(1)} E_{21}^{(2)} E_{32}^{(3)}, T_{21}^L = E_{13}^{(1)} E_{32}^{(2)} E_{21}^{(3)}; T_{12}^R = E_{12}^{(1)} E_{23}^{(2)} E_{31}^{(3)}, T_{21}^R = E_{23}^{(1)} E_{12}^{(2)} E_{31}^{(3)}$.

Rigidity. $\lambda^L = \lambda^R = c_1 c_2 / (2c_{12}) = 1/2 = \int_0^1 (1-t) dt$.

Serre. $2\alpha_1 + \alpha_2 \notin \Phi(\mathfrak{sl}_3) \Rightarrow (\mathfrak{sl}_3)_{2\alpha_1 + \alpha_2} = 0 \Rightarrow [e_1, [e_1, e_2]] = 0$.

60.3 The root quadrilateral at filtration 3: the coefficient $\frac{1}{3}$

For $A_3(\mathfrak{sl}_4)$, chain $i \sim j \sim k$ with $[E_i, E_k] = 0$. The BCH: $\text{mult}_{XYZ} \log(e^X e^Y e^Z) = \frac{1}{3}[X, [Y, Z]]$ when $[X, Z] = 0$. Direct verification: $\frac{1}{4} + \frac{1}{12} = \frac{1}{3}$ from the general formula $\frac{1}{4}[[X, Y], Z] + \frac{1}{12}[X, [Y, Z]] + \frac{1}{12}[Y, [X, Z]]$ with $[X, Z] = 0$ and Jacobi. The $n = 3$ beta integral: $\int_0^1 (1-t)^2 dt = 1/3$.

Root-space one-dimensionality: $\dim(\mathfrak{sl}_4)_{\alpha_1 + \alpha_2 + \alpha_3} = 1$. All multilinear Lie monomials proportional to E_{ijk} .

60.4 The gauge-gravity complexity dichotomy

	A_∞ products m_k	Coproduct Δ_z
Gauge (CS)	$m_k = 0 \ (k \geq 3)$	nontrivial Yangian
Gravity (Vir)	$m_k \neq 0 \ \forall k$	strictly primitive

DS transports $\mathbf{L} \rightarrow \mathbf{M}$: preserves Koszulness, destroys formality. The resolvent tree formula $m_k^W = \Sigma_{\text{Catalan}}(m_2^{\text{aff}} \circ h_{\text{DS}})$ generates the infinite tower.

60.5 The free-field nilpotent kernel

$\Theta = \beta(x) \otimes \gamma(y) - \gamma(x) \otimes \beta(y)$, $\Theta^2 = 0$. Transport $T(u, u_0) = 1 + \Theta \log \frac{u+x-y}{u_0+x-y}$, monodromy $M = 1 + 2\pi i \Theta$. Contrast: Heisenberg $R = \exp(k/z)$ (full exponential); $\beta\gamma$: $R = 1 +$ (linear) (nilpotent truncation). Wakimoto: $Y_{\text{dg}}(\mathfrak{g}) = H^*(Y_{\text{free}}, Q_{\text{DS}})$.

60.6 The curvature-braiding dichotomy at genus 1

Coisson bracket $c_o := \{a_{(o)} b\}$ controls decoupling. $c_o = 0$: quasi-periodic elliptic r -matrix with exact Cartan gauge-twist defect; structures decouple (Heisenberg, lattice). $c_o \neq 0$: quasi-periodic, defect $2\eta_\tau$ couples curvature to braiding (affine KM, Virasoro). Genus-1 R -matrix for Virasoro: $r_1(z; \tau) = (c/2)(\wp(z; \tau) + E_2(\tau)/12) + 2T E_2(\tau)$.

60.7 The three-language spine

Datum	Physical (DNP25)	Spectral (Latyntsev)	Geometric (COZZ26)
R -matrix	OPE exchange	fact. iso	stable envelope
YBE	Ward identity	fact. axiom	braid relation
Strict.	root mult. 1	by constr.	by constr.

Common object: $\overline{B}^{\text{ord}}(\mathcal{A})$ on $\text{FM}_k(\mathbb{C}) \times \text{Conf}_k^<(\mathbb{R})$.

60.8 Three Koszul duality operations and the origin of the spectral parameter

The $\text{SC}^{\text{ch},\text{top}}$ operad has two colours, producing **three** distinct Koszul duality operations on a chiral algebra $\mathcal{A}$:

Operation	Bar complex	Output	Example for $\widehat{\mathfrak{g}}_k$
Chiral KD	$B^{\text{ch}}(\mathcal{A})$ on $\text{Conf}_n(X)/\Sigma_n$	chiral alg. $\mathcal{A}_{\text{ch}}^!$	$\widehat{\mathfrak{g}}_{-k-2h^\vee}$
E_1 -chiral KD	$\tilde{B}^{\text{ord}}(\mathcal{A})$ on $\text{Conf}_n^{\text{ord}}(X)$	SC-alg. $\mathcal{A}_{\text{line}}^!$	$Y_h(\mathfrak{g})$
Pure E_1 KD	$T^c(s^{-1}\tilde{\mathcal{A}})$, classical	bare A_∞ alg.	$U(\mathfrak{g})^!$

The dg-shifted Yangian is the E_1 -**chiral Koszul dual**, not the pure E_1 Koszul dual. The spectral parameter u comes from the closed-colour data retained by the ordered chiral bar complex: the bar differential $d_{\tilde{B}^{\text{ord}}}$ uses OPE residues from the curve (closed-colour data absorbed as internal differential in the open-colour projection). A pure E_1 bar complex (forgetting chirality) would discard this data and produce a bare A_∞ algebra without spectral parameter.

The key structural fact: the ordered chiral bar complex $\tilde{B}^{\text{ord}}(\mathcal{A})$ is the *open-colour projection* of the $\text{SC}^{\text{ch},\text{top}}$ -bar complex. “Open-colour projection” means: project to the E_1 operadic structure (deconcatenation coproduct) while *absorbing* the closed-colour data as the internal differential. The coalgebra structure (deconcatenation) is purely combinatorial; the differential (OPE residues) carries all the holomorphic/chiral geometry.

60.9 The E_1 -chiral algebra structure on the Yangian

The $\text{SC}^{\text{ch},\text{top}}$ -algebra structure on $\mathcal{A}_{\text{line}}^!$ is concretely realised by the derived additive KZ connection (Theorem ??). The dictionary:

E_1 -chiral algebra datum	KZ connection realisation
operation spaces	$\text{Conf}_n^{\text{ord}}(\mathbb{A}_u^1)$
spectral OPE	$A_n = \sum_{i < j} \Omega_{ij}(z_j - z_i) d(z_j - z_i)$
associativity	$\mathbb{D}_n^2 = 0$ (spectral Kohnno = YBE)
braiding	$R(z) = \text{regularised holonomy}$

The E_1 -chiral algebra is NOT a vertex algebra (no state-field correspondence with conformal grading). It is an algebra over the operad of ordered configuration spaces on $\mathbb{A}^1$, with operations encoded by a flat meromorphic connection. The RTT relation $R_{12}(u - v)T_1(u)T_2(v) = T_2(v)T_1(u)R_{12}(u - v)$ is the mixed-colour operation $\mu_{1,2}$ (one closed insertion at spectral separation $u - v$, two ordered open insertions).

60.10 The curvature of the Yangian

If $\mathcal{A}_{\text{line}}^! = Y_h(\mathfrak{g})$ is viewed as an E_1 -chiral algebra on $\mathbb{A}_u^1$, Vol I’s machinery gives it a modular characteristic $\kappa(Y_h(\mathfrak{g}))$.

Complementarity. By Vol I Theorem C (complementarity): $\kappa(\mathcal{A}) + \kappa(\mathcal{A}_{\text{line}}^!) = \alpha$ where $\alpha = 0$ for affine KM and $\alpha = 13$ for Virasoro. So:

$$\kappa(Y_h(\mathfrak{g})) = -\kappa(\widehat{\mathfrak{g}}_k) = -\frac{\dim \mathfrak{g} (k + h^\vee)}{2h^\vee} \quad (\text{affine KM}),$$

$$\kappa(Y^{\text{dg}}(\text{Vir}_c)) = \frac{26-c}{2} \quad (\text{Virasoro}).$$

Genus tower of the Yangian. $\sum_{g \geq 1} F_g(Y^{\text{dg}}(\text{Vir}_c)) x^{2g} = \frac{26-c}{2} (\hat{A}(ix) - 1)$. At $c = 26$: all $F_g = 0$ (critical string $\Rightarrow$ anomaly cancellation). At $c = 13$: the genus tower equals minus itself under Koszul duality (gravitational S-duality).

The “Yangian of the Yangian”. If $Y_{\text{dg}}(\mathfrak{g})$ is an E_1 -chiral algebra, it has its own open-colour Koszul dual $Y_{\text{dg}}(Y_{\text{dg}}(\mathfrak{g}))$. By bar-cobar-bar involution $(\Omega(\bar{B}(\Omega(\bar{B}(\mathcal{A})))) \simeq \mathcal{A}$, this should recover $\widehat{\mathfrak{g}}_k$. The double Koszul dual is the original: The *full* $\text{SC}^{\text{ch}, \text{top}}$ double Koszul dual $(\mathcal{A}^!)^! = \mathcal{A}$ (Theorem ??) operates on both colours simultaneously and does recover $\widehat{\mathfrak{g}}_k$ -- the central extension survives because it is a *closed-colour* datum (the double pole in the holomorphic OPE), transported through the Verdier/Ran duality, not through the open-colour ordered bar.

Explicit open-colour double bar for $\mathfrak{sl}_2$: what it recovers and what it misses. The ordered chiral bar complex $\bar{B}^{\text{ord}}(Y_{\hbar}(\mathfrak{sl}_2))$ on $\mathbb{A}_u^1$ recovers the *current algebra* $\mathfrak{sl}_2[t]$ (**without** central extension):

- *Degree 1*: Yangian generators E_n, F_n, H_n map to current modes J_n^a .
- *Degree 2*: The spectral OPE has only *simple* poles ($[E(u), F(v)] \sim \hbar/(u-v) \cdot (\dots)$). The bar differential extracts only the zeroth product: $[E_n, F_m] = H_{n+m}$. No central term $k \delta_{n+m,0}$ appears -- that requires a *double* pole, which the spectral OPE does not have.
- The $E-E$ OPE has pole at $u-v = \hbar$ (*shifted off the collision diagonal*), so $d_{\text{res}}(s^{-1}E \otimes s^{-1}E) = 0$, correctly reproducing $[e, e] = 0$.
- *Degree 3*: $d^2 = 0$ is the classical YBE for $r(u) = P/u$, automatic by Jacobi.

The central extension is invisible to the open-colour double bar. The parameter $\hbar = 1/(k+2)$ is a deformation parameter of $Y_{\hbar}(\mathfrak{g})$ that encodes the level k of the original affine algebra, but its recovery as a *central extension* requires the closed-colour (Verdier/Ran) direction of the full $\text{SC}^{\text{ch}, \text{top}}$ Koszul duality. The open-colour double bar $(\mathcal{A}_{\text{line}}^!)_{\text{line}}^!$ recovers $U(\mathfrak{g}[t])$ (the current algebra without central extension), not $\widehat{\mathfrak{g}}_k$.

The gauge-gravity fingerprint. $\kappa(\mathcal{A}) + \kappa(\mathcal{A}^!) = 0$ for gauge theories (anomaly cancellation); $= 13$ for gravity (irreducible gravitational anomaly). The double bar $B^{E_1\text{-ch}}(B^{\text{ch}}(\mathcal{A}))$ has no curvature obstruction in the gauge case (both genus towers cancel) but residual curvature 13 in the gravitational case. The vanishing at $c = 26$ is the critical string condition.

6I The two-colour Koszul duality architecture

The ordered and symmetric chiral bar complexes expose two projections of the bulk–boundary datum governed by $\text{SC}^{\text{ch}, \text{top}}$. They should not be conflated with a literal self-dual $\text{SC}^{\text{ch}, \text{top}}$ -coalgebra. Each projection has its own duality operation and output category.

	Bar complex	Duality	Output type	For $\widehat{\mathfrak{g}}_k$
Closed colour	$B^{\text{ch}}(\mathcal{A})$ on $\text{Ran}(X)/\Sigma_n$	D_{Ran} (Verdier)	chiral algebra on X	$\widehat{\mathfrak{g}}_{-k-2\hbar^\vee}$
Open colour	$\bar{B}^{\text{ord}}(\mathcal{A})$ on $\text{Conf}_n^{\text{ord}}(X)$	$H^*(-)^\vee$ (linear)	Yangian (E_1 + spectral)	$Y_{\hbar}(\mathfrak{g})$
Pure E_1	$T^c(s^{-1}\bar{\mathcal{A}})$ (classical)	$H^*(-)^\vee$	bare A_∞	$U(\mathfrak{g})^!$

Why two different outputs. Verdier duality D_{Ran} operates on D-modules on $\text{Ran}(X)$ and produces a factorisation *algebra* from a factorisation coalgebra. The output is automatically a chiral algebra on X (same species as the input). Linear duality $H^*(-)^\vee$ operates on chain complexes and produces an associative algebra. The spectral parameter $u = 1/z$ in the Yangian comes from the curve coordinate z surviving in the ordered bar differential (which uses OPE residues from all pole orders $a_{(n)}b$, $n \geq 0$). Verdier duality on the *symmetric* bar complex quotients out the ordering and with it the spectral parameter.

The R -matrix as cross-colour datum. The descent from ordered to unordered is R -twisted:

$$B_n^\Sigma(\mathcal{A}) \simeq (\pi_{n,*} \bar{B}_n^{\text{ord}}(\mathcal{A}))^{\Sigma_n, \mathcal{L}_R},$$

where $\pi_n : \text{Conf}_n^{\text{ord}}(X) \rightarrow \text{Conf}_n(X)$ is the covering map and $\mathcal{L}_R$ is the local system determined by the braiding. This reduces to ordinary invariants or coinvariants only in the pole-free case. For the pole-free BD-commutative subclass of E_∞ -chiral algebras (no OPE singularities): $R(z) = \tau$ (the flip), descent is trivial, both duals carry equivalent information. For E_∞ -chiral algebras with OPE poles (Heisenberg, affine KM, Virasoro -- still E_∞ , since all vertex algebras are E_∞ -chiral): $R(z) \neq \tau$ (derived from the local OPE via analytic continuation), and $\mathcal{A}_{\text{line}}^!$ carries strictly more structure than $\mathcal{A}_{\text{ch}}^!$. For genuinely E_1 -chiral algebras (nonlocal, Etingof–Kazhdan quantum vertex algebras): $R(z) \neq \tau$ and is independent in put, not derivable from a local OPE.

Operad-level explanation. At the operad level $\text{Com}^{\text{ch}!} = \text{Lie}^{\text{ch}}$ (Francis–Gaitsgory), while $\text{Ass}^{\text{ch}!} = \text{Ass}^{\text{ch}}$ in the associative lane. The two-coloured quadratic dual of the Swiss-cheese structure is not literally the same operad: the closed colour dualises to the Lie/chiral side, the open colour to the associative side, and the mixed operations dualise to the corresponding shuffle/brace module. Thus an ordered bar construction produces a dual two-colour algebra only after choosing the relevant coloured Koszul model; $\mathcal{A}_{\text{ch}}^!$ and $\mathcal{A}_{\text{line}}^!$ are projections of that constructed dual datum, not consequences of unqualified self-duality.

The Heisenberg test case. For $\mathcal{H}_k: \mathcal{A}_{\text{ch}}^! = \text{Sym}^{\text{ch}}(V^*)$ (a commutative chiral algebra with $\kappa = -k$; isomorphic to $\mathcal{H}_{-k}$ as a chiral algebra but $\mathcal{H}_k^! \neq \mathcal{H}_{-k}$ as objects in the present classification). $\mathcal{A}_{\text{line}}^! = Y(u(1)) = k[h_0, h_1, \dots]$ (the abelian Yangian with spectral parameter u). Pure E_1 KD produces $\wedge(J^{*(n)})$ (an exterior algebra, no spectral parameter). All three are genuinely different. The “accident” that $Y(u(1)) \simeq \mathcal{H}_{-k}$ as mode algebras is abelian-specific; for $\widehat{\mathfrak{g}}_k$ with $\mathfrak{g}$ non-abelian, $Y_h(\mathfrak{g})$ and $\widehat{\mathfrak{g}}_{-k-2h^\vee}$ are utterly different algebras (different mode structures, different relations, different operadic homes).

The bridge: Conjecture ??. The pole-order (“commutator”) filtration on $\mathcal{A}$ kills all OPE poles of order ≥ 2 , leaving $\text{gr}_{\text{com}} \mathcal{A} = V_0(\mathfrak{g})$ (the level-zero chiral algebra, which is E_∞). The conjecture predicts $\text{gr}_{\text{com}}(\mathcal{A}_{\text{line}}^!) \simeq (\text{gr}_{\text{com}} \mathcal{A})_{\text{FG}}^!$ on the Koszul locus: the associated graded of the Yangian recovers the Francis–Gaitsgory dual of the level-zero algebra. The stratification spectral sequence (E_1 page = FG bar complex, convergence proved) provides the controlled interpolation. The filtration compatibility of the bar differential remains the sole gap.

When do the two duals agree? When $\mathcal{A}$ lies in the pole-free BD-commutative subclass of E_∞ -chiral algebras: $R(z) = \tau$, descent is trivial, both duals carry equivalent information.

When do they disagree? When $\mathcal{A}$ is E_∞ -chiral with OPE poles (all interesting vertex algebras: Heisenberg, affine KM, Virasoro -- these are still E_∞ , since all vertex algebras are E_∞ -chiral): $R(z)$ carries nontrivial spectral dependence derived from the local OPE, and $\mathcal{A}_{\text{line}}^!$ (the Yangian) is strictly richer than $\mathcal{A}_{\text{ch}}^!$ (the FG dual). The R -matrix is the data killed by the Σ_n -coinvariant step.

62 Chromaticity in the bar-cobar programme

62.1 What is proved

Two results in the core monograph place the chromatic programme on firm algebraic ground.

- (i) **Smashing localisation commutes with factorization homology** (Theorem 1.71 in the core chapter on logarithmic HT monodromy): for a locally constant spectral factorization algebra $\mathcal{A}$ on an m -manifold M and a smashing localisation L , $L(\int_M \mathcal{A}) \simeq \int_M L\mathcal{A}$. Since $L_{E(n)}$ -localisation is smashing, chromatic height is compatible with the local-to-global passage once the theory is spectralized.
- (ii) **The scalar genus tower is $\hat{A}(ix)$** (Theorem in the Rosetta stone chapter): $F^{\text{tot}}(\mathcal{A}; \hbar) = (\kappa(\mathcal{A})/\hbar^2) \cdot (\hbar/2)/\sin(\hbar/2)$. The generating function $(x/2)/\sin(x/2) = \hat{A}(ix)$ is the Wick rotation of the q^0 term of the Witten genus characteristic series. The higher q -powers correspond to the Eisenstein-weighted genus-1 corrections: on E_τ , each pole of order $2k$ in the OPE generates a correction weighted by $E_{2k}(\tau)$.

62.2 The genus tower as a chromatic shadow

The genus tower has three structural features connecting it to chromatic homotopy theory:

- *Curvature as periodicity generator.* The element $u = \kappa(\mathcal{A}) \cdot \omega_g$ in the transgression algebra controls the curved bar structure $d^2 = \kappa \cdot \omega_g$. Its invertibility creates Clifford periodicity; its vanishing ($\kappa = 0$, the critical level) collapses the genus tower. This parallels v_n -periodicity in chromatic homotopy theory.
- *Eisenstein weights and formal groups.* The genus-1 bar differential replaces the additive kernel $1/z$ by the Weierstrass ζ -function $\zeta(z|\tau)$, the logarithm of the elliptic formal group $\hat{E}_\tau$. The formal group of E_τ has height ≤ 2 (height 1 ordinary, height 2 supersingular), so genus-1 data accesses chromatic height ≤ 2 . The Eisenstein series $E_{2k}(\tau)$ for $k \geq 2$ are sections of $\omega^{\otimes 2k}$ on $\mathcal{M}_{1,1}$; E_2 is quasi-modular (the Arakelov defect).
- *Clutching and redshift.* The non-separating clutching $D_1: B^{(g)} \rightarrow B^{(g+1)}$ adds one handle, increasing $\dim(J)$ by 1 and the p -divisible group height $\text{ht}(J[p^\infty])$ by 2 (since $\text{ht} = 2 \cdot \dim$ for abelian varieties). Whether this is a geometric counterpart of chromatic redshift (K -theory raises height by 1) is an open analogy—the factor-of-2 mismatch must be understood.

62.3 Anti-patterns: what is *not* true

AP-CHR The classical bar complex $B(\mathcal{A})$ is a chain complex over $\mathbb{C}$, hence an $H\mathbb{C}$ -module, hence rational: $L_{K(n)}(B(\mathcal{A})) = 0$ for all $n \geq 1$. The entire classical bar-cobar theory is chromatic height 0. No OPE pole produces positive-height chromatic data in the linear theory. The additive formal group $\hat{\mathbb{G}}_a$ of the spectral-parameter composition law has height ∞ over $\mathbb{F}_p$ (not height 1; height 1 is $\hat{\mathbb{G}}_m$). Chromatic height ≥ 1 enters only after spectralization.

AP-RED Koszul duality $\mathcal{A} \mapsto \mathcal{A}^!$ reflects the curvature ($\kappa \mapsto -\kappa$ for KM, $\kappa \mapsto 13 - \kappa$ for Virasoro) but does not raise chromatic height. The clutching D_1 raises p -divisible group height by 2, not 1. Formal-group height is a p -local invariant: it requires reduction mod p , not a complex parameter.

AP-TOWER The chromatic convergence theorem (Hopkins–Ravenel) uses $L_{E(n)}$ -localisation (Johnson–Wilson), not $L_{K(n)}$. The $K(n)$ -localisations do not form a tower with natural transition maps.

62.4 The four-stage factorization

The algebraic route from a chiral algebra to a chromatic invariant:

$$\mathcal{A} \xrightarrow{\text{bar}} B_{\text{mod}}(\mathcal{A}) \xrightarrow{\text{FT}_{\text{rel}}} \mathcal{Z}_{\mathcal{A}} \xrightarrow{\text{sp. lift}} \mathcal{Z}_{\mathcal{A}}^{\text{sp}} \xrightarrow{L_{E(n)}} \mathcal{Z}_{\mathcal{A},n}.$$

Stages 1–2 (modular bar construction and relative Feynman transform) are proved. Stage 3 (spectralization) is the fundamental open problem. Stage 4 (chromatic localisation) is automatic from the smashing-localisation theorem.

62.5 Conjectural chromatic directions

The following directions are retained as conjectural tests. Each item records the mathematical obstruction that must be solved before the idea can enter the stable core.

- (i) **Synthetic spectra and the chiral bar complex.** The bigrading (holomorphic weight, topological arity) parallels Pstrągowski’s synthetic bigrading (stem, Adams filtration). The curvature κ plays the role of τ : at $\kappa = 0$ the theory decouples. *Errors found:* the $\tau = 0$ fibre of the synthetic SC operad should be a semidirect product, not a coproduct; the Adams SS for $B(\mathcal{A})$ is trivial over $\mathbb{C}$.
- (ii) **Transchromatic phenomena in the genus tower.** The genus tower should correspond to the chromatic tower, with genus g accessing heights $\leq 2g$ via $\text{Jac}(\Sigma_g)$. *Errors found:* the height-genus identification used $L_{K(n)}$ instead of $L_{E(n)}$; the transition maps $\overline{\mathcal{M}}_g \rightarrow \overline{\mathcal{M}}_{g-1}$ do not exist; formal-group heights were assigned over $\mathbb{C}$ without p -local specification; p -divisible group heights were off by factor 2.
- (iii) **The chromatic modular functor.** The open-sector category $C_{\partial, \mathcal{A}}$ should be fully dualizable, producing a 3d framed TQFT via the cobordism hypothesis. The Stolz–Teichner programme predicts the spectral lift yields tmf-valued invariants. *Errors found:* the tmf weight sign was wrong ($\eta^{-\kappa}$ has weight $-\kappa/2$, not $\kappa/2$); the Hurewicz image claim was absurdly strong.
- (iv) **Telescope conjecture failure.** Non-formal SC-algebras ($m_k \neq 0$ for $k \geq 3$) should exhibit telescope conjecture failure at heights ≥ 2 . *Errors found:* classical A_{∞} non-formality is a characteristic-zero phenomenon and cannot directly cause p -local spectral telescope failure; blueshift was claimed for continuous $C_p \subset U(1)$ actions when the theorem applies to finite group actions on finite spectra; $\text{SL}_2(\mathbb{Z})$ has p -torsion only for $p = 2, 3$.
- (v) **Physical ramifications.** The chromatic programme has potential physical consequences: the perturbative/non-perturbative divide (formal vs non-formal SC structure) may relate to the telescope watershed; the $c = 26$ dichotomy ($\kappa_{\text{eff}} = 0$) corresponds to chromatic decoupling; the arithmetic fracture square (rationalization + p -completion) may correspond to the perturbative/non-perturbative split in QFT. These remain speculative analogies.

The unstable source material (1710 lines) is preserved in `archive/source_tex/chromatic_frontier_quarantined.tex`.

63 The Wick rotation architecture

The Wick rotation $x \mapsto ix$ in the genus tower $\sum F_g x^{2g} = \kappa_{\text{eff}}(\hat{A}(ix) - 1)$ is not an isolated substitution. It is the surface expression of a five-layer structure that connects the generating function to the formal

group, the modular group, the operadic decomposition, and the chromatic filtration. Each layer is forced by the previous.

63.1 Layer 1: the sign absorption

The $\hat{A}$ -genus $\hat{A}(x) = (x/2)/\sinh(x/2)$ has alternating Bernoulli coefficients. The substitution $x \mapsto ix$ converts $\sinh(ix/2) = i \sin(x/2)$, producing $\hat{A}(ix) = (x/2)/\sin(x/2)$. The factor $i^{2g} = (-1)^g$ on each monomial x^{2g} cancels the alternation, leaving the all-positive Faber–Pandharipande integrals $\lambda_g^{\text{FP}} = (2^{2g-1} - 1) |B_{2g}| / (2^{2g-1} (2g)!)$. The coefficients decay as $\lambda_g^{\text{FP}} \sim 2/(2\pi)^{2g}$; the scalar genus series converges for $|x| < 2\pi$. The Borel transform is entire -- no resurgence is needed at the scalar level.

The physical content: the alternating-sign series is the index of the Dirac operator (Lorentzian signature), while the all-positive series is the Hodge integral (Euclidean signature). The monograph works in the Euclidean frame throughout; the connection to the Witten genus (conventionally stated in the sinh convention) requires un-Wick-rotating.

63.2 Layer 2: the Eisenstein structure at genus 1

On an elliptic curve E_τ , the genus-0 bar kernel $1/(z - w)$ is replaced by the Weierstrass ζ -function $\zeta(z - w|\tau)$. The propagator expansion $h(u; \tau) = u^{-1} + \sum_{k \geq 1} c_k(\tau) u^{2k-1}$ has coefficients

$$c_k(\tau) = (-1)^k \frac{(2\pi)^{2k}}{(2k)!} B_{2k} E_{2k}(\tau).$$

Each OPE pole of even order $2k$ generates a genus-1 correction weighted by $E_{2k}(\tau)$. The propagator has only odd powers of u (by the oddness of θ_1), so odd-order poles contribute nothing.

For Heisenberg (max pole 2): only E_2 enters. The Coisson bracket $c_o = \{a_{(o)} b\}$ vanishes, so the quasi-periodicity defect of E_2 acts in the Cartan channel alone -- curvature and braiding decouple.

For Virasoro (max pole 4): E_2 from the double pole and E_4 from the quartic pole. The Coisson bracket is nonzero, so the E_2 defect couples curvature to braiding -- the two structures entangle. This is the genus-1 avatar of the curvature-braiding open question (Conclusion, §??, item (5)).

For $\mathcal{W}_3$ (max pole 6): E_2, E_4, E_6 . The truncation by pole order is the genus-1 shadow of the pole-order classification (classes **G/L/C/M**).

The quasi-modularity of E_2 is the Arakelov defect: under $\tau \mapsto -1/\tau$, $E_2(-1/\tau) = \tau^2 E_2(\tau) + 12\tau/(2\pi i)$. The anomalous term is proportional to $\kappa(\mathcal{A})$ and is the genus-1 bar curvature $d^2 = \kappa \cdot \omega_1$. The non-holomorphic completion $\hat{E}_2 = E_2 - 3/(\pi \text{Im } \tau)$ restores modularity at the cost of holomorphicity -- the holomorphic anomaly equation.

63.3 Layer 3: the genus tower as Wick rotation anomaly

This is the central reformulation.

The genus-1 partition function $Z_1^{\text{eff}}(\tau) = \eta(\tau)^{-\kappa_{\text{eff}}}$ transforms under the modular S -transform $\tau \mapsto -1/\tau$ as $Z_1(-1/\tau) = (-i\tau)^{-\kappa_{\text{eff}}/2} Z_1(\tau)$. The modular weight is $-\kappa_{\text{eff}}/2$.

- $\kappa_{\text{eff}} = 0$ ($c = 26$): the weight vanishes, Z_1 is S -invariant, the genus tower is identically zero, and the Wick rotation is an exact symmetry.
- $\kappa_{\text{eff}} \neq 0$: the weight is nonzero, Z_1 has a modular anomaly, the genus tower $F_g \neq 0$ at every genus, and the Wick rotation is broken. The degree of breaking is measured by $F_g = \kappa_{\text{eff}} \cdot \lambda_g^{\text{FP}}$.

The Cardy formula is the composition of the S -transform (which plays the structural role of Wick rotation at genus 1; see Layer 5 for the precise distinction) with saddle-point extraction: $S_{\text{Cardy}} = 2\pi\sqrt{c\Delta/6}$ for shifted energy $\Delta = L_o - c/24$. The quartic pole produces κ , the curvature produces $d^2 = \kappa \cdot \omega_1$, the Wick rotation anomaly produces F_g , the Cardy extraction produces the entropy. The chain is:

$$\text{quartic pole} \longrightarrow \kappa \xrightarrow{+\kappa_{\text{ghost}}} \kappa_{\text{eff}} \longrightarrow d^2 = \kappa_{\text{eff}} \cdot \omega_g \longrightarrow F_g \neq 0 \longrightarrow S_{\text{Cardy}}.$$

The Witten genus is the elliptic repair of this anomaly. The q^0 piece $\hat{A}(ix)$ has anomalous modular weight $-\kappa(\mathcal{A})/2$ (intrinsic; $-\kappa_{\text{eff}}/2$ after ghost subtraction); the higher q -powers (the Eisenstein corrections from Layer 2) exactly cancel the anomaly, producing a modular form -- the Witten genus. The Eisenstein corrections are the Wick rotation repair terms.

63.4 Layer 4: formal groups and the chromatic boundary

The spectral-parameter composition law of the bar complex is the additive formal group $\hat{\mathbb{G}}_a$, with formal group law $F(x, y) = x + y$. The endomorphism ring is $\text{End}(\hat{\mathbb{G}}_a) = \mathbb{C}$, and the Wick rotation $x \mapsto ix$ is the endomorphism $[i]$.

Upon spectralization (the passage from chain complexes over $\mathbb{C}$ to spectra), the formal group changes: at height 1, $\text{End}(\hat{\mathbb{G}}_m) = \mathbb{Z}_p$; at height ≤ 2 , $\text{End}(\hat{E}_\tau)$ is an order in a quadratic field or quaternion algebra. These arithmetic endomorphism rings generically exclude i : the Wick rotation does not survive the passage from height 0 (rational) to positive height (spectral).

There is no spectral Wick rotation. The substitution $x \mapsto ix$ preserves $\hat{\mathbb{G}}_a$ (additive) but not $\hat{\mathbb{G}}_m$ (multiplicative) or $\hat{E}_\tau$ (elliptic). This is the mechanism behind the anti-pattern AP-CHR: the classical bar-cobar theory is chromatic height 0, and the Wick rotation lives in this classical setting. Chromatic height ≥ 1 enters only after spectralization, which is the fundamental open problem (Stage 3 of the four-stage pipeline).

Five obstructions to spectralization

The following are open problems, not conjectures. Each identifies a specific obstruction to Stage 3 of the pipeline $\mathcal{A} \rightarrow B_{\text{mod}}(\mathcal{A}) \rightarrow Z_{\mathcal{A}} \rightarrow Z_{\mathcal{A}}^{\text{sp}} \rightarrow Z_{\mathcal{A},n}$.

- (i) **Base ring problem.** $B(\mathcal{A})$ is a chain complex over $\mathbb{C}$. Spectra are not $\mathbb{C}$ -modules: one needs an integral form $B(\mathcal{A})_{\mathbb{Z}}$, a chain complex over $\mathbb{Z}$ with $B(\mathcal{A})_{\mathbb{Z}} \otimes_{\mathbb{Z}} \mathbb{C} \simeq B(\mathcal{A})$. For Kac–Moody algebras at integral level, such forms exist (Garland). For general chiral algebras, no canonical integral form is known.
- (ii) **Operadic coherence.** $\text{SC}^{\text{ch}, \text{top}}$ involves $\mathbb{C}$ -linear algebraic data: FM compactification of configurations in $\mathbb{C}$, logarithmic weight forms, residue pairings. Lifting to an operad in spectra requires understanding the interaction between holomorphic structure and stable homotopy theory.
- (iii) **Formal group identification.** The genus-1 bar differential (Movement I) uses the formal group of E_τ , but as complex-analytic functions (Weierstrass ζ), not as formal group laws over $\mathbb{Z}$. Connecting to tmf requires the formal group law over $\mathbb{Z}[c_4, c_6, \Delta^{-1}]$.
- (iv) **No genus tower maps.** There are no natural maps $\overline{\mathcal{M}}_g \rightarrow \overline{\mathcal{M}}_{g-1}$. The genus tower is an expansion indexed by g , not a sequential limit. The chromatic convergence analogy (limit over $E(n)$ -localizations) has no direct geometric counterpart on the moduli side.

- (v) **Height discrepancy.** Non-separating clutching D_1 raises p -divisible-group height by 2 ($\text{ht} = 2 \cdot \dim$ for abelian varieties). Chromatic redshift (THH/TAQ) raises chromatic height by 1. The factor-of-2 mismatch is unexplained.

The sole exception: the elliptic curve E_i with $j = 1728$ has CM by $\mathbb{Z}[i]$, so its formal group admits $[i]$. At this single j -invariant, Wick rotation is compatible with height ≤ 2 . Whether this plays a role in the spectralization problem is unknown.

63.5 Layer 5: operadic and the three signatures

The HT theory on $\mathbb{C}_z \times \mathbb{R}_t$ has the Swiss-cheese operad $\text{SC}^{\text{ch}, \text{top}}$ with operation spaces $\text{FM}_k(\mathbb{C}) \times \text{Conf}_k^<(\mathbb{R})$. The $\mathbb{C}$ -direction is holomorphic; the $\mathbb{R}$ -direction is ordered.

Three signatures, with different operadic status:

- **Lorentzian** (2, 1): the light-cone constraint $|\Delta z| = |\Delta t|$ is treated as a gauge/local-shadow heuristic in the HT twist. No equality of Lorentzian causal operads with $\text{SC}^{\text{ch}, \text{top}}$ is asserted.
- **Euclidean** (3, 0): the E_3 operad $C_*(\text{FM}_k(\mathbb{R}^3))$, one-coloured, fully symmetric. There is no Dunn-additivity promotion of the raw bicoloured $\text{SC}^{\text{ch}, \text{top}}$ -algebra to E_3 . An E_3^{top} structure appears only after the topologisation/cohomology hypotheses supplied by inner stress tensors.
- **Ultra-Lorentzian** (1, 2): one spatial direction, no complex structure, outside the HT framework.

The R -matrix $R(z)$ is the Wick rotation datum: it mediates the descent from the ordered bar complex $\overline{B}^{\text{ord}}(\mathcal{A})$ on $\text{Conf}_k^<(\mathbb{R})$ to the unordered bar complex on $\text{Conf}_k(\mathbb{C})$, via the Σ_k -covering. Without the R -matrix, the descent loses information.

The S -transform is not the Wick rotation. The modular S -transform $\tau \mapsto -1/\tau$ acts on the *closed* colour (the complex structure of E_τ); the Wick rotation of $\mathbb{R}_t$ acts on the *open* colour. They share the Casimir datum $c_o = \{a_{(o)} b\}$ as coupling constant but are operadically orthogonal: the identification of S with Wick rotation is a 2d worldsheet perspective that does not survive the 3d HT lift.

63.6 Open questions from this architecture

- (i) **The Mellin/Laplace/Wick triangle.** Three integral transforms operate along the topological direction $\mathbb{R}$:

- The *Laplace transform* $r(z) = \int_0^\infty e^{-\lambda z} \{\cdot, \lambda \cdot\} d\lambda$ converts the λ -bracket (closed colour) to the R -matrix (open colour). It is the additive Fourier transform on $(\mathbb{R}_+, +)$.
- The *Mellin transform* $\tilde{A}(\Delta, z, \bar{z}) = \int_0^\infty \omega^{\Delta-1} A(\omega, z, \bar{z}) d\omega$ converts energy to conformal dimension. It is the multiplicative Fourier transform on $(\mathbb{R}_+, \times)$.
- The change of variables $\omega = e^t$ converts Mellin in ω to bilateral Laplace in t . The Wick rotation $t \mapsto -it$ corresponds to $z \mapsto iz$ in the additive Laplace variable, converting exponential decay (Euclidean convergence) to oscillation (Lorentzian causality).

The celestial OPE *does* reduce to the bar differential: this is already proved (Theorems ?? and ??). The passage from the HT boundary to the celestial boundary is the topological integration $\int_0^\infty dt$ (the E_1 -coinvariant projection), *not* a Wick rotation. But the Wick rotation and the celestial transfer meet at $c = 26$: the genus tower vanishes (Wick-invariant) and the effective scalar partition function trivialises. In the BMS limit $c \rightarrow \infty$, the Wick rotation anomaly $\kappa_{\text{eff}} \rightarrow \infty$ is maximal: the BMS algebra inherits the strongest possible breaking of Wick-rotation symmetry.

- (ii) **The curvature-braiding criterion.** At genus 1, the Coisson bracket $c_o = \{a_{(o)}b\}$ controls whether curvature and braiding decouple ($c_o = 0$: Heisenberg, lattice VOAs) or entangle ($c_o \neq 0$: Kac–Moody, Virasoro). Does this dichotomy persist at genus $g \geq 2$, with the Fay trisecant identity playing the role of the Arnold relation?
- (iii) **Borel summability of the shadow obstruction tower.** The scalar genus tower converges. The shadow obstruction tower for class **M** at $|c| < 6$ diverges geometrically with growth rate $\rho > 1$. Is this divergent series Borel summable? The expected Stokes structure: in the Euclidean frame, the Borel singularities lie on the real axis at $\xi = 1/\rho$; the Wick rotation moves them to the imaginary axis, clearing the integration contour. The modular S -transform at the $q \rightarrow 1$ boundary plays the structural role of Borel resummation.
- (iv) **Monstrous moonshine at rank 24.** For a rank-24 lattice VOA: $\kappa = 24$ and $Z_1(V_\Lambda; \tau) = \Theta_\Lambda(\tau)/\eta(\tau)^{24}$. The special expression $\eta(\tau)^{-24} = 1/\Delta(\tau)$ is the rank-24 Heisenberg oscillator factor, not a general lattice-VOA character. For the Leech lattice: $Z_1(V_{\text{Leech}}; \tau) = \Theta_{\text{Leech}}(\tau)/\eta(\tau)^{24} = j(\tau) - 720$ (exact). The discriminant $\Delta = \eta^{24}$ generates the 576-fold periodicity of tmf . Does the bar complex at rank 24 encode any of the Monster moonshine structure beyond the rational shadow?
- (v) **The algebraic-analytic gap.** The monograph works entirely on the algebraic side: Koszulness (a homological condition on the bar complex) replaces unitarity (a metric condition on the Hilbert space) as the structural input. Reflection positivity requires a $*$ -structure compatible with the OPE, which is not formulated here. The order-reversal involution $R_A: B^{\text{ch}}(A^{\text{op}}) \xrightarrow{\sim} B^{\text{ch}}(A)^{\text{cop}}$ provides the categorical backbone of time-reversal, but the *positivity* condition $\langle \Omega, R_A(\cdot) \rangle \geq 0$ is invisible to the bar complex alone. The Verdier pairing (pairing A with $A^!$) and the BPZ inner product (pairing A with itself) are distinct structures: they coincide only at the self-dual point $c^* = \alpha_N/2$. Koszulness and unitarity are logically independent: Vir_c at $c < 0$ is Koszul but non-unitary, while unitary non-formal algebras exist. The Segal comparison conjecture (algebraic factorization algebra $\rightarrow$ geometric functorial QFT) and the Osterwalder–Schrader reconstruction (Euclidean $\rightarrow$ Lorentzian) remain the open interfaces between the algebraic and analytic frameworks. Whether the Koszul locus is contained in the Kontsevich–Segal convergence domain is an unresolved question at this interface.

64 Trefoil verification: Kontsevich integral from the bar complex

The spectral R -matrix $R(z) = \exp(\hbar k \Omega/z)$ of $\widehat{\mathfrak{sl}}_{2,k}$ (Proposition ?? of spectral-braiding-core) recovers the Kontsevich integral of the trefoil $3_1 = \widehat{\sigma}_1^3$ at degrees ≤ 3 . This verifies Example ?? of spectral-braiding-frontier with explicit formulas.

R-matrix eigenvalues on $V = \mathbb{C}^2$

The $\mathfrak{sl}_2$ Casimir on $V \otimes V$ decomposes as $\Omega|_{\text{Sym}^2(V)} = 1/4$ and $\Omega|_{\Lambda^2(V)} = -3/4$, so the braid closure $\text{tr}_M(R(z_{12})^3)$ with $R^3 = \exp(3\hbar k \Omega/z)$ gives

$$Z_V(3_1) = 3 e^{3\hbar k/(4z)} + e^{-9\hbar k/(4z)},$$

where the multiplicities $3 = \dim \text{Sym}^2(V)$, $1 = \dim \Lambda^2(V)$ arise from the quantum trace at leading order.

Degree-by-degree matching

Degree	Coefficient	Source
1	$z_1 = \frac{3}{2} \theta$	Writhe $w = 3$, each crossing contributes $\pm 1/2$
2	$z_2 = \frac{1}{24} D_2^{\text{conn}}$ after normalization	$B_2/4 = 1/24$; normalization-dependent
3	IHX class	Arnold relation; numerical weight-system normalization not fixed here

The degree-1 term is pure framing ($z_1 = w/2$, removed by framing correction). In the standard Kontsevich normalization, the first nontrivial Vassiliev invariant is $z_2(3_1) = 1/24$.

The coefficient $1/24$

The coincidence of $1/24$ in three contexts -- the degree-2 trefoil invariant, the leading q -exponent coefficient in $F_1 = -\kappa \log \eta(\tau)$, and the constant term $G_2(\tau) = -1/24 + \dots$ -- traces to a common source: the curved bar structure $d_B^2 = \kappa(\mathcal{A}) \omega_1$ at genus 1, whose perturbative coefficient in the Eisenstein basis is $B_2/4 = 1/24$. The trefoil, as the closure of σ_1^3 , probes the minimal nontrivial configuration on $\text{FM}_2(\mathbb{C}) \times \text{Conf}_2(\mathbb{R})$.

The $\mathfrak{sl}_2$ weight-system evaluation depends on the chosen normalization of the connected degree-2 chord class and is not used here as an independent theorem.

Degree 3: IHX from Arnold

For the affine lineage, one-loop exactness (Theorem ??) forces the transferred cohomology operation m_3^H to vanish. The degree-3 bar differential involves only pairwise collisions, landing in the chord diagram sector. The Arnold relation $\alpha_{12} \wedge \alpha_{23} + \alpha_{23} \wedge \alpha_{31} + \alpha_{31} \wedge \alpha_{12} = 0$ on $H^\bullet(\text{Conf}_3(\mathbb{C}))$, with $\mathfrak{g}$ -valued Casimir decorations, becomes $D_I + D_H - D_X = 0$: the IHX relation is *derived* from FM geometry, not imposed.

Status

The degree-2 coefficient is verified in the stated normalization. At degree 3, Arnold cancellation gives structural IHX evidence; the numerical weight-system normalization is not fixed in this summary. The full identification $Z_{A_\infty}(K) = Z(K)$ at all orders remains conjectural (Theorem ??). At degree 4, the chord diagram algebra $\mathcal{A}_4(\mathfrak{sl}_2)$ has dimension 3; the symmetry factor matching between FM boundary strata and chord diagram multiplicities becomes the first genuinely nontrivial combinatorial test.

Question 64.1 (Beyond the affine lineage). For non-formal Swiss-cheese structures ($m_3 \neq 0$, e.g. Virasoro), the degree-3 bar differential includes trivalent vertices. The Kontsevich integral, built from pairwise $d \log$ forms, sees only the chord diagram quotient. Capturing the higher m_k requires the full A_∞ partition function $Z_{A_\infty}(K)$. The degree-3 divergence between the chord diagram framework and the A_∞ framework is the first point where class L and class M separate in the knot invariant.

65 $\mathfrak{sl}_3$ monodromy identification: first rank-2 test

Setup

Let $\mathfrak{g} = \mathfrak{sl}_3$, $h^\vee = 3$, $\rho = \omega_1 + \omega_2$. Inner product: $(\omega_i, \omega_j) = (A^{-1})_{ij}$ with $A^{-1} = \frac{1}{3} \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$. Quadratic Casimir: $c_2(\lambda) = (\lambda, \lambda + 2\rho)$. Cubic Casimir: $c_3(p, q) = \frac{1}{18}(p - q)(2p + q + 3)(p + 2q + 3)$; note $c_3(p, q) = -c_3(q, p)$ (distinguishes a rep from its contragredient).

Test 1: braiding on $V \otimes V$

$V = V_{(1,0)} = \mathbb{C}^3$. Clebsch–Gordan: $V \otimes V \cong V_{(2,0)} \oplus V_{(0,1)}$. Split Casimir eigenvalues (via $\Omega|_{V_\nu} = \frac{1}{2}(c_2(\nu) - 2c_2(\lambda))$): $\Omega|_{V_{(2,0)}} = 2/3$, $\Omega|_{V_{(0,1)}} = -4/3$. Steinberg connection: $\nabla_{\mathfrak{G}} = d + \Omega dz / ((k+3)z)$. Monodromy ($q = e^{i\pi/(k+3)}$):

$$\text{Mon}|_{V_{(2,0)}} = q^{4/3}, \quad \text{Mon}|_{V_{(0,1)}} = q^{-8/3}.$$

These match $U_q(\mathfrak{sl}_3)$ exactly ($\check{R}$ -matrix eigenvalues up to permutation sign on $\Lambda^2 V$). The cubic Casimir does *not* appear: C_2 alone distinguishes the two summands. Same mechanism as $\mathfrak{sl}_2$.

Test 2: associator on $V^{\otimes 3}$ — the cubic Casimir enters

$V^{\otimes 3} \cong V_{(3,0)} \oplus 2 \cdot V_{(1,1)} \oplus V_{(0,0)}$ ($\mathbf{10} \oplus 2 \cdot \mathbf{8} \oplus \mathbf{1}$). The two copies of $V_{(1,1)}$ arise from intermediate channels: $\mathbf{8}_{\text{sym}}$ (via $V_{(2,0)}$) and $\mathbf{8}_{\text{anti}}$ (via $V_{(0,1)}$) in the (12) -grouping.

The Drinfeld–KZ associator at order $\hbar^3 = 1/(k+3)^3$ involves the antisymmetric double commutator $\mathcal{A} = [\Omega_{12}, [\Omega_{12}, \Omega_{23}]] - [\Omega_{23}, [\Omega_{23}, \Omega_{12}]]$. By the Fierz identity for $\mathfrak{sl}_3$,

$$f_{ace} f_{bde} = \frac{2}{3}(\delta_{ab} \delta_{cd} - \delta_{ad} \delta_{bc}) + d_{ace} d_{bde} - d_{ade} d_{bce},$$

the double commutator decomposes into a Casimir piece (present for all $\mathfrak{g}$) and a d -tensor piece $\mathcal{D}_{123}^{(-)}$ (vanishes for $\mathfrak{sl}_2$, nonzero for $\mathfrak{sl}_3$). The d -tensor piece produces **off-diagonal mixing** between the two copies of $V_{(1,1)}$, proportional to

$$\Delta c_3 = c_3(2, 0) - c_3(0, 1) = \frac{35}{9} + \frac{10}{9} = 5.$$

This is the first genuinely higher-rank phenomenon: the cubic Casimir enters the monodromy through the *associator*, not through the R -matrix eigenvalues.

Verification and conclusion

By one-loop exactness of $V^k(\mathfrak{sl}_3)$ at generic k (Theorem ??), the bar-complex reduced connection *is* the KZ connection ($m_k = 0$ for $k \geq 3$). Therefore the bar-complex associator reproduces the Drinfeld–KZ associator identically, including the cubic Casimir contribution. By Drinfeld–Kohno, the monodromy identifies with $U_q(\mathfrak{sl}_3)$.

Summary: The $\mathfrak{sl}_3$ test confirms Theorem ?? at rank 2. C_2 controls the diagonal part of the monodromic structure (braiding eigenvalues). C_3 controls the off-diagonal part (multiplicity-space mixing in the associator). For $\mathfrak{sl}_2$, $C_3 = 0$ and the off-diagonal channel is absent.

66 Genus-1 curved bar complex: stable summary

The genus-1 propagator

On $E_\tau = \mathbb{C}/(\mathbb{Z} + \mathbb{Z}\tau)$, the Arakelov-normalised propagator is $\eta^{(1)}(u; \tau) = h(u; \tau) + R(u; \tau)$, where $h(u; \tau) = \partial_u \log \mathfrak{P}_1(u|\tau)$ is meromorphic and $R(u; \tau) = 2\pi i \operatorname{Im}(u)/\operatorname{Im}\tau$ is the smooth Arakelov correction. The Laurent expansion of h near $u = 0$ has only odd powers:

$$h(u; \tau) = \frac{1}{u} + \sum_{k=1}^{\infty} c_k(\tau) u^{2k-1}, \quad c_k(\tau) = (-1)^k \frac{(2\pi)^{2k}}{(2k)!} B_{2k} E_{2k}(\tau),$$

with $c_1 = -(\pi^2/3)E_2$, $c_2 = -(\pi^4/45)E_4$, $c_3 = -(2\pi^6/945)E_6$.

Arnold relation failure at genus 1

At genus 0, the Arnold relation $\sum_{\text{cyc}} \eta_{12}^{(0)} \wedge \eta_{23}^{(0)} = 0$ ensures $d_{\text{fib}}^2 = 0$. At genus 1, decompose $\eta^{(1)} = h + R$:

- (a) $\sum_{\text{cyc}} h_{12} \wedge h_{23} = 0$ by the Fay trisecant identity (the holomorphic Arnold relation holds on the universal cover).
- (b) $\sum_{\text{cyc}} R_{12} \wedge R_{23}$: smooth, no residue contribution.
- (c) The cross-terms $h \wedge R + R \wedge h$ produce the Arnold defect:

$$\sum_{\text{cyc}} \eta_{12}^{(1)} \wedge \eta_{23}^{(1)} = \omega_1, \quad \omega_1 = \frac{i}{2 \operatorname{Im}\tau} dz \wedge d\bar{z}, \quad \int_{E_\tau} \omega_1 = 1.$$

The Arnold defect is the Arakelov (1, 1)-form ω_1 . This is the genus-1 source of curvature.

The fibre differential on $[s^{-1}T|s^{-1}T]$

The residue of $\eta^{(1)} \cdot T(z_1)T(z_2)$ at $u = 0$ gives:

$$d_{\text{fib}}^{(1)}[s^{-1}T|s^{-1}T] = s^{-1} \left(:TT: - \frac{2\pi^2}{3} E_2(\tau) \cdot T - \frac{c\pi^4}{90} E_4(\tau) \cdot \mathbf{1} \right).$$

The three terms: genus-0 normal-ordered product (from $1/u$ times $:TT:$); the E_2 -correction (from $c_1 u$ times $2T/u^2$); the E_4 -contact term (from $c_2 u^3$ times $(c/2)/u^4$).

For general weights h_a, h_b :

$$d_{\text{fib}}^{(1)}[s^{-1}a|s^{-1}b] = s^{-1} \left(a_{(-1)}b + \sum_{k=1}^{\lfloor (h_a+h_b)/2 \rfloor} c_k(\tau) \cdot a_{(2k-1)}b \right),$$

where the sum terminates because $a_{(n)}b = 0$ for $n \geq h_a + h_b$. The odd OPE products $a_{(2k-1)}b$ pair with the odd propagator coefficients $c_k(\tau)u^{2k-1}$. Each even-order OPE pole has a genus-1 Eisenstein shadow.

Curvature: $d_{\text{fib}}^{(1),2} = \kappa \cdot \omega_1$

Decompose $\eta^{(1)} = h + R$. In the double residue computing d_{fib}^2 : (a) $h \cdot h$ vanishes by Fay trisecant; (b) $R \cdot R$ vanishes by smoothness; (c) the cross-terms $h \cdot R + R \cdot h$ produce the curvature. The cross-term extracts:

- from h : the leading OPE coefficient via residue,
- from R : the Arakelov class $\bar{\partial} R = -\omega_{\text{Ar}}$,

with the coefficient given by the modular characteristic $\kappa(\text{Vir}_c) = c/2$ (defined via zeta-regularised partition function, not by the literally divergent trace $\text{Tr}(L_o)$). Result:

$$d_{\text{fib}}^{(1),2}[s^{-1}a] = \frac{c}{2} \cdot \omega_1 \cdot [s^{-1}a].$$

The higher OPE poles contribute to the genus-1 *differential* (the E_2, E_4 corrections) but not to the *curvature* d^2 . The curvature sees only the modular characteristic.

Genus-1 free energy and the critical dichotomy

$F_1^{\text{intr}} = (c/2) \cdot (1/24) = c/48$; $F_1^{\text{eff}} = ((c-26)/2) \cdot (1/24) = (c-26)/48$. On a fixed torus: $Z_1(\tau) = \eta(\tau)^{-\kappa}$. The $\hat{A}$ -genus check: $\hat{A}(ix) - 1 = (1/24)x^2 + \dots$ gives $F_1 = \kappa/24$. Confirmed.

	$c \neq 26$	$c = 26$
κ_{eff}	$(c-26)/2 \neq 0$	0
F_1^{eff}	$(c-26)/48 \neq 0$	0
$d_{\text{fib}}^{(1),2}$	$((c-26)/2) \omega_1$	0
Genus tower	nonzero at all g	vanishes identically
Regime	curved bar	flat bar

What is genuinely new

- The Arnold defect mechanism.** The genus-1 Arnold relation does not fail wholesale: the holomorphic summand $h \wedge h$ still cancels (Fay trisecant). The defect comes entirely from the non-holomorphic Arakelov correction R , whose $\bar{\partial}$ -inexactness produces the $(1,1)$ -form ω_1 . This is a controlled failure: the defect is a *scalar* times ω_1 , not a matrix-valued form.
- Eisenstein shadows of OPE poles.** The genus-1 propagator pairs odd powers $c_k u^{2k-1}$ with even-order OPE poles $a_{(2k-1)} b/u^{2k}$, producing Eisenstein-weighted corrections. Each pole order $2k$ in the OPE casts a genus-1 shadow $E_{2k}(\tau)$. The double pole $\rightarrow E_2$ (quasi-modular, one-loop self-energy); the quartic pole $\rightarrow E_4$ (modular, contact term).
- Curvature vs. differential separation.** Higher OPE poles affect the differential but not the curvature. The curvature $d^2 = \kappa \cdot \omega_1$ depends only on κ (the modular characteristic), not on the detailed pole structure. This is the genus-1 manifestation of the universal formula $d^2 = \kappa \cdot \omega_g$.

67 Celestial amplitudes from the bar complex: stable summary

Audit of the celestial amplitude computation against the core chapters: Theorem ?? (gluon OPE), Theorem ?? (graviton OPE), Theorem ?? (MHV integral), Theorem ?? (helicity splitting), and Remark ?? (colour-ordered = ordered-bar).

Audit of the collision residue computation

- (i) **Gluon.** The λ -bracket $\{J^a_\lambda J^b\} = f^{ab}_c J^c + k\kappa^{ab}\lambda$ Laplace-transforms to $r^{\text{Lap}}(z) = f J^c/z + k\kappa/z^2$. After $d \log$ absorption ($z^{-n} \mapsto z^{-(n-1)}$), the structure-constant term drops to z^0 and the level term survives at z^{-1} : $r^{\text{KM}}(z) = k\Omega/z$. Colour-ordered projection of the Casimir yields f^{ab}_c . *Matches Fan–Fotopoulos–Taylor.*
- (ii) **Graviton.** The Virasoro λ -bracket $\{T_\lambda T\} = (\partial + 2\lambda)T + \frac{c}{12}\lambda^3$ Laplace-transforms to $\partial T/z + 2T/z^2 + (c/2)/z^4$ (using $\int_0^\infty \lambda^3 e^{-\lambda z} d\lambda = 6/z^4$, so $(c/12)(6/z^4) = (c/2)/z^4$). After $d \log$ absorption: $r^{\text{Vir}}(z) = (c/2)/z^3 + 2T/z$. The ∂T term drops. *Matches Pasterski–Shao–Strominger.* The two poles are the Weinberg soft factor ($r_1 = 2T$) and the gravitational anomaly ($r_3 = c/2$).
- (iii) **MHV at $n = 4$.** Conditional on the stated normalisation of the FM orientation, the bar-complex integral $\int_{\overline{\text{FM}}_4(\mathbb{C})} \omega_4^{(+,-,-,+)} \wedge \nu_4$ localises to three channels $D_{\{1,2\}}, D_{\{2,3\}}, D_{\{3,4\}}$. Each $d \log(z_i - z_j)$ residue produces $\langle ij \rangle^{-1}$ via the spinor-helicity identification $z_i - z_j \sim \langle ij \rangle / (\lambda_i^2 \lambda_j^2)$. The anti-holomorphic pairing of the two negative-helicity insertions supplies the numerator $\langle 23 \rangle^4$. Under these identifications this recovers the Parke–Taylor form; the statement is a normalization check, not an independent proof of the physical amplitude.

Colour-ordered structure and the ordered bar

Colour-ordered celestial amplitudes are ordered-bar objects (Remark ??): they live on $\text{Conf}_n^<(\mathbb{C})$, not the symmetric quotient. The Parke–Taylor denominator $\prod_{i=1}^n \langle i, i+1 \rangle^{-1}$ is the $d \log$ residue on ordered configurations -- the holomorphic colour of the ordered bar differential. Full amplitudes are recovered by R -matrix descent: $\mathcal{M}_n = \sum_{\sigma \in \Sigma_n/\text{cyc}} R_\sigma \cdot \mathcal{M}_n^{\text{ord}}(\sigma)$. This is the celestial manifestation of the two-colour architecture of Part ??, consistent with the E_∞ locality of $\widehat{\mathfrak{g}}_k$: the ordered bar carries strictly more data than the symmetric bar when OPE poles are present, and the R -matrix descent is genuinely twisted, not naive.

Residual questions

- (a) **NMHV and double twisting morphisms.** NMHV amplitudes (three negative helicities) require a double pairing between $\overline{B}^{\text{ch}}(\mathcal{A})$ and $\overline{B}^{\text{ch}}(\mathcal{A}')$: two bulk propagators connecting three anti-holomorphic insertions to the holomorphic skeleton. *Is the BCFW recursion a statement about the A_∞ structure of the twisting-morphism space?*
- (b) **Graviton MHV from $\overline{B}^{\text{ch}}(\text{Vir}_c)$.** At $n = 4$, the graviton MHV amplitude $M_4 = \langle 23 \rangle^8 / (\langle 12 \rangle^2 \langle 23 \rangle^2 \langle 34 \rangle^2 \langle 41 \rangle^2)$ has doubled power relative to gluons, reflecting spin 2. In the bar complex, this doubling should arise from the quartic OPE pole of Virasoro (versus the quadratic pole of Kac–Moody), producing extra $\langle ij \rangle$ powers per collision. *Precise integral formula is a target for future computation.*

68 Virasoro spectral R -matrix: stable extract

Classical r -matrix (verified)

The Laplace transform of the Virasoro λ -bracket $\{T_\lambda T\} = \partial T + 2T\lambda + \frac{c}{12}\lambda^3$ is (using $\int_0^\infty \lambda^n e^{-\lambda z} d\lambda = n!/z^{n+1}$):

$$r^L(z) = \frac{\partial T}{z} + \frac{2T}{z^2} + \frac{c/2}{z^4}.$$

This is the *Laplace kernel*: same pole orders as the OPE. The *collision residue* (bar-theoretic r -matrix: $d \log$ absorbs one power) is

$$r^{\text{coll}}(z) = \frac{c/2}{z^3} + \frac{2T}{z}.$$

The $\partial T/z$ term becomes regular after absorption and drops. Both formulae match the established manuscript (3d_gravity.tex lines 1000, 3123; examples-worked.tex line 112).

Classical Yang–Baxter equation (verified)

The CYBE for $r^L(z)$ follows from the PVA Jacobi identity. Writing $I = \{T_\lambda \{T_\mu T\}\}$, $II = \{T_\mu \{T_\lambda T\}\}$, $III = \{\{T_\lambda T\}_{\lambda+\mu} T\}$:

$$I - II = (\lambda - \mu) \partial T + 2(\lambda^2 - \mu^2) T + \frac{c}{12}(\lambda - \mu)(\lambda + \mu)^3 = III.$$

The central-term cancellation $\frac{c}{12}(\lambda^4 - \mu^4 + 2\lambda\mu(\lambda^2 - \mu^2)) = \frac{c}{12}(\lambda - \mu)(\lambda + \mu)^3$ is verified by factoring. Under Laplace transform this becomes the CYBE with spectral parameters $(u, u + v, v)$. The Arnold interpretation: the three commutator terms are the three codimension-1 boundary strata of $\text{FM}_3(\mathbb{C})$; Stokes forces their sum to vanish (same mechanism as $d_B^2 = 0$).

Quantum corrections: two-source structure

The quantum R -matrix $R(z) = \text{id} + \hbar r^{(1)}(z) + \hbar^2 r^{(2)}(z) + \dots$ (with $\hbar = 12/c$) receives corrections from two sources at each order:

- (i) *Iterated monodromy*: path-ordered exponential of the classical r -matrix (Chen iterated integrals of r^L);
- (ii) A_∞ *corrections*: the ternary operation m_3^{Vir} (and higher) correct the shifted KZ connection.

The two sources partially cancel via the Stasheff identity $\partial m_3 + m_2 \circ m_2 = 0$. On the diagonal (level-0 to level-0 component $|h_1, h_2\rangle \rightarrow |h_1, h_2\rangle$):

$$R(z)|_{\text{diag}} = \exp\left(\frac{c/2}{z^4} \hbar + \frac{2h_1 h_2}{z^4} \hbar^2 + O(\hbar^3)\right).$$

The leading term is the abelian phase; the $2h_1 h_2 \hbar^2 / z^4$ is the first genuine quantum correction.

Degenerate truncation (verified)

On the $(2, 1)$ -degenerate representation $V_{h_{2,1}}$, all A_∞ corrections vanish (null vectors kill $m_3, m_4, \dots$), and $R(z)$ is computed exactly by the BPZ equation. Monodromy eigenvalues: $e^{\pm i\pi b a_2}$, matching the Ponsot–Teschner kernel.

Ponsot–Teschner comparison: status

- (1) *Classical limit*: $r^L(z)$ matches the $b \rightarrow 0$ saddle of the fusion kernel. Verified.
- (2) *Degenerate eigenvalues*: exact match via BPZ. Verified.
- (3) *First quantum correction at level 0*: the $2h_1h_2/z^4$ coefficient matches the leading term of the Zamolodchikov one-loop determinant W_1 in the heavy limit $h_i = c\epsilon_i/6$. Verified at leading order.
- (4) *Full identification* $R = \mathbb{F}^{\text{PT}}$: conjectural. Gap: analytic continuation from integer k (affine DS transport) to continuous c via the Faddeev modular double.

Normalization notes

- (E1) The mode expansion eq. (3.5) of $r_{12}^L(z)$ has powers z^{-n-1} and z^{-n} in the denominator that can become positive powers of z —this is a notational error (confuses position-space field $T(z)$ with the tensor $r_{12}(z)$). The subsequent eq. (3.6) and level-1 computation bypass this and are correct.
- (E2) The skew-symmetry discussion (lines 145–151 of the diff) claims $r(-z) + r_{21}(z) = (c/2)/z^4 + (c/2)/z^4 = 0$; the two central terms ADD rather than cancel, so the equation should read $r_{12}(-z) + r_{21}(z) = (c/z^4) \text{id} \otimes \text{id}$ (a scalar, hence compatible with CYBE up to coboundary).
- (E3) The classical-limit comparison (Observation 5.1) writes $W_0 \supset P_1P_2/z^2$ but then matches against $2h_1h_2/z^4 \cdot 1/c$; these are different z -powers. The heavy-limit statement in Theorem 4.1(v) is more carefully formulated and should be preferred.

69 Virasoro m_4 and m_5 : stable formulas

Two parallel computations of the Virasoro A_∞ operations m_4 and m_5 were cross-checked. The explicit formulas agree with Propositions ??–?? of §27. This section records the stable formulas with corrected structural claims, the Shapovalov inner product derivation of the quartic contact invariant, and the OPE of $:TT:$ with T .

69.1 m_4 : forced by the Stasheff relation

With $m_1 = \partial \neq 0$ (translation), the arity-4 Stasheff relation is read in the chiral λ -formalism after applying sesquilinearity to the translation terms. In this convention it has the direct form $m_4 + \text{Obs}_4 = 0$, where Obs_4 involves only m_2 and m_3 . Thus $m_4 = -\text{Obs}_4$ is *forced*, not a free cocycle. If one writes instead $\partial(m_4) + \text{Obs}_4 = 0$, a genuine contracting homotopy must be inserted before solving for m_4 .

$$\begin{aligned}
m_4(T^4; \lambda_{12}, \lambda_{23}, \lambda_{34}) &= (\lambda_{23} + 2\lambda_{34}) \partial^2 T \\
&+ (5\lambda_{12}^2 - 4\lambda_{12}\lambda_{23} + 3\lambda_{12}\lambda_{34} - 5\lambda_{23}^2 + 10\lambda_{23}\lambda_{34} + 4\lambda_{34}^2) \partial T \\
&+ 2(\lambda_{12}^3 + 2\lambda_{12}^2\lambda_{23} + 3\lambda_{12}^2\lambda_{34} - 2\lambda_{12}\lambda_{23}^2 - 4\lambda_{12}\lambda_{23}\lambda_{34} + 4\lambda_{12}\lambda_{34}^2 \\
&\quad - \lambda_{23}^3 - 2\lambda_{23}^2\lambda_{34} + 6\lambda_{23}\lambda_{34}^2) T \\
&+ \frac{c}{12}(\lambda_{12}^5 + 2\lambda_{12}^4\lambda_{23} + 3\lambda_{12}^4\lambda_{34} + 4\lambda_{12}^3\lambda_{23}\lambda_{34} + 2\lambda_{12}^3\lambda_{34}^2 \\
&\quad - 2\lambda_{12}\lambda_{23}^4 - 4\lambda_{12}\lambda_{23}^3\lambda_{34} - 4\lambda_{12}\lambda_{23}\lambda_{34}^3 + 2\lambda_{12}\lambda_{34}^4 \\
&\quad - \lambda_{23}^5 - 2\lambda_{23}^4\lambda_{34} + 6\lambda_{23}\lambda_{34}^4).
\end{aligned}$$

Symmetric point: $m_4(T^4; \lambda, \lambda, \lambda) = 3\lambda \partial^2 T + 13\lambda^2 \partial T + 14\lambda^3 T + \frac{7c}{12} \lambda^5$. No $\partial^3 T$ term (associahedron K_4 cell structure). All T -dependent coefficients are c -independent.

69.2 Quartic contact invariant from the Shapovalov form

At conformal weight 4, the Shapovalov matrix in the basis $(\partial^2 T, :TT:) = (2L_{-4}|o\rangle, L_{-2}^2|o\rangle)$ is

$$S^{(4)} = \begin{pmatrix} 5c & 3c \\ 3c & c(c+8)/2 \end{pmatrix}, \quad \det S^{(4)} = \frac{c^2(5c+22)}{2}, \quad (S^{(4)})^{-1} = \frac{1}{c(5c+22)} \begin{pmatrix} c+8 & -6 \\ -6 & 10 \end{pmatrix}.$$

The quartic contact invariant $\mathfrak{Q}_{\text{Vir}}^{\text{contact}} = 10/[c(5c+22)]$ is the $(2, 2)$ -entry of $(S^{(4)})^{-1}$, with poles at $c = 0$ and $c = -22/5$ (Lee–Yang).

69.3 The projected normally ordered kernel for $\{ :TT:_{\lambda} T \}$

By the Dong lemma, the T -linear/projected component used by the homotopy transfer is:

$$\{ :TT:_{\lambda} T \} = -\partial^2 T \cdot \lambda - \frac{5}{2} \partial T \cdot \lambda^2 - \frac{4}{3} T \cdot \lambda^3 - \frac{c}{40} \lambda^5.$$

This is not the full normally ordered OPE; omitted channels are projected away in the HPL computation of m_4 . The normally ordered product provides the chain homotopy between the full (associative) OPE and the (non-associative) λ -bracket.

69.4 m_5 : explicit polynomials P_1 and P_0

$$\begin{aligned}
m_5(T^5; \lambda_{12}, \lambda_{23}, \lambda_{34}, \lambda_{45}) &= -\partial^4 T - (2\lambda_{12} + 4\lambda_{23} + \lambda_{34} + 3\lambda_{45}) \partial^3 T \\
&+ (3\lambda_{12}^2 - 16\lambda_{12}\lambda_{23} - 6\lambda_{12}\lambda_{45} - 13\lambda_{23}^2 + 7\lambda_{23}\lambda_{34} \\
&\quad - 9\lambda_{23}\lambda_{45} - 7\lambda_{34}^2 + 3\lambda_{34}\lambda_{45} - 3\lambda_{45}^2) \partial^2 T \\
&+ P_1(\lambda) \partial T + P_0(\lambda) T + \frac{c}{12} Q_5(\lambda),
\end{aligned}$$

where the degree-3 and degree-4 polynomials are:

$$\begin{aligned}
P_1 &= 10\lambda_{12}^2\lambda_{23} - 9\lambda_{12}^2\lambda_{34} + 14\lambda_{12}^2\lambda_{45} - 5\lambda_{12}\lambda_{23}^2 - 20\lambda_{12}\lambda_{23}\lambda_{34} - 49\lambda_{12}\lambda_{23}\lambda_{45} \\
&\quad - 8\lambda_{12}\lambda_{34}^2 + 13\lambda_{12}\lambda_{34}\lambda_{45} - 5\lambda_{12}\lambda_{45}^2 + 2\lambda_{23}^3 - 9\lambda_{23}^2\lambda_{34} - 45\lambda_{23}^2\lambda_{45} \\
&\quad - 3\lambda_{23}\lambda_{34}^2 + 41\lambda_{23}\lambda_{34}\lambda_{45} + \lambda_{23}\lambda_{45}^2 - 9\lambda_{34}^3 - 5\lambda_{34}^2\lambda_{45} + 5\lambda_{34}\lambda_{45}^2 - 3\lambda_{45}^3, \\
P_0 &= 4\lambda_{12}^3\lambda_{23} - 2\lambda_{12}^3\lambda_{34} + 2\lambda_{12}^3\lambda_{45} + 10\lambda_{12}^2\lambda_{23}^2 - 4\lambda_{12}^2\lambda_{23}\lambda_{34} + 14\lambda_{12}^2\lambda_{23}\lambda_{45} \\
&\quad - 8\lambda_{12}^2\lambda_{34}^2 - 6\lambda_{12}^2\lambda_{34}\lambda_{45} + 8\lambda_{12}^2\lambda_{45}^2 - 4\lambda_{12}\lambda_{23}^3 - 4\lambda_{12}\lambda_{23}^2\lambda_{34} \\
&\quad - 16\lambda_{12}\lambda_{23}^2\lambda_{45} - 16\lambda_{12}\lambda_{23}\lambda_{34}^2 - 16\lambda_{12}\lambda_{23}\lambda_{34}\lambda_{45} - 32\lambda_{12}\lambda_{23}\lambda_{45}^2 \\
&\quad + 4\lambda_{12}\lambda_{34}^3 - 4\lambda_{12}\lambda_{34}^2\lambda_{45} + 8\lambda_{12}\lambda_{34}\lambda_{45}^2 + 4\lambda_{12}\lambda_{45}^3 \\
&\quad + 2\lambda_{23}^3\lambda_{34} + 2\lambda_{23}^3\lambda_{45} - 8\lambda_{23}^2\lambda_{34}^2 - 16\lambda_{23}^2\lambda_{34}\lambda_{45} - 32\lambda_{23}^2\lambda_{45}^2 \\
&\quad + 6\lambda_{23}\lambda_{34}^3 + 46\lambda_{23}\lambda_{34}\lambda_{45}^2 + 2\lambda_{23}\lambda_{45}^3 \\
&\quad - 2\lambda_{34}^4 - 16\lambda_{34}^3\lambda_{45} + 10\lambda_{34}^2\lambda_{45}^2 - 2\lambda_{34}\lambda_{45}^3 - 2\lambda_{45}^4.
\end{aligned}$$

Symmetric point: $m_5(T^5; \lambda, \lambda, \lambda, \lambda) = -\partial^4 T - 10\lambda \partial^3 T - 41\lambda^2 \partial^2 T - 84\lambda^3 \partial T - 68\lambda^4 T - \frac{17c}{6} \lambda^6$. All symmetric-point coefficients are negative (the five-graviton vertex is uniformly attractive). $Q_5(\lambda, \dots, \lambda) = -34\lambda^6$. The scalar $-17c/6 = (c/12)(-34)$ maintains the $c/12$ prefactor.

69.5 Corrected structural rules

The parallel computations each stated structural rules with minor errors. The stable versions:

- (a) *Weight rule (corrected)*. The coefficient of $\partial^j T$ in m_k has λ -degree $k - 1 - j$. Equivalently, $\text{wt}(\text{output}) + \deg_\lambda = k + 1$. This is conformal weight conservation: k inputs of weight 2 produce output of total weight $k + 1$ (after accounting for the degree- $(k - 1)$ operation and the desuspension).
- (b) *Scalar degree (corrected)*. The scalar polynomial Q_k has degree $k + 1$ (not $2k - 3$), consistent with (a) at $j = 0$ and output weight 0 for a c -number.
- (c) *Central charge isolation*. In every m_k , the central charge enters exclusively through the scalar term $\frac{c}{12} Q_k(\lambda)$. All T -dependent coefficients are c -independent.
- (d) *Leading term at $\lambda = 0$ (corrected)*. The claim “ m_k vanishes at $\lambda = 0$ ” is false. At zero spectral parameters: $m_2(T, T; 0) = \partial T$, $m_3(T^3; 0, 0) = \partial^2 T$, $m_4(T^4; 0, 0, 0) = 0$, $m_5(T^5; 0, \dots, 0) = -\partial^4 T$. The vanishing of m_4 at $\lambda = 0$ reflects the absence of a degree-0 leading coefficient (the associahedron K_4 cell-structure effect).

k	Leading term	$j + \deg_\lambda$	$\deg(Q_k)$	$m_k _{\lambda=0}$
2	∂T	$1 = k-1$	$3 = k+1$	∂T
3	$\partial^2 T$	$2 = k-1$	$4 = k+1$	$\partial^2 T$
4	$(\lambda_{23} + 2\lambda_{34})\partial^2 T$	$3 = k-1$	$5 = k+1$	0
5	$-\partial^4 T$	$4 = k-1$	$6 = k+1$	$-\partial^4 T$

Observation 69.1 (Symmetric-point coefficient sequences). The symmetric-point evaluations produce the array:

k	$\partial^{k-2}T$	$\dots$	∂^2T	∂T	T	scalar/ λ^{k+1}
2	1			2		$c/12$
3	1			5	6	$c/4$
4			3	13	14	$7c/12$
5	-1	-10	-41	-84	-68	$-17c/6$

The sign alternation between m_4 (positive) and m_5 (negative) is the Koszul sign from the bar desuspension s^{-1} . The scalar coefficients $c/12, c/4, 7c/12, -17c/6$ (i.e. 1, 3, 7, -34 times $c/12$) grow rapidly: the A_∞ tower does not truncate for generic c .

70 Soft graviton theorems from the A_∞ tower

The shadow connection hierarchy decomposes the MC element Θ_{Vir_c} by arity into celestial soft factors. The λ -bracket $\{T_\lambda T\} = \partial T + 2T\lambda + (c/12)\lambda^3$ encodes the OPE, and the dictionary between pole order and soft order is:

λ -bracket term	OPE pole	Soft order	Physical content
∂T	$(z-w)^{-1}$	$S^{(0)}$ (leading)	Weinberg
$2T\lambda$	$(z-w)^{-2}$	$S^{(1)}$ (subleading)	Cachazo–Strominger
$(c/12)\lambda^3$	$(z-w)^{-4}$	T - T channel	Central extension (engine)

PROPOSITION 70.1 (*Leading celestial Ward shadow*). The arity-2 shadow S_2 gives the two-dimensional celestial Ward shadow of Weinberg’s leading soft factor: $S_i^{(0)} = \partial_{z_i}/(z_o - z_i)$. In bar-complex language, $d_{\overline{B}}$ on $[s^{-1}T \mid s^{-1}O_i]$ extracts $T_{(o)}O_i = \partial O_i$.

PROPOSITION 70.2 (*Subleading celestial Ward shadow*). The subleading soft factor is $S_i^{(1)} = h_i/(z_o - z_i)^2$, the double-pole residue of S_2 . The mode $T_{(1)}O_i = h_iO_i$ is the L_o eigenvalue: the $2T\lambda$ term in the λ -bracket.

PROPOSITION 70.3 (*Conditional sub-subleading shadow from m_3*). The sub-subleading celestial shadow requires the ternary A_∞ operation m_3 : the binary OPE $T(z)O_i(w)$ has at most a double pole for primary O_i , so $S_i^{(2)}|_{\text{binary}} = 0$. The first non-trivial sub-subleading contribution is the quartic contact: $\mathfrak{Q}^{\text{contact}} = 10/(c(5c + 22))$. The quartic pole $(c/12)\lambda^3$ is the *engine*: it generates the non-associativity forcing m_3 , which forces m_4 , and so on.

PROPOSITION 70.4 (*Conditional soft-shadow hierarchy*). Conditional on the celestial Mellin bridge and the usual IR normalisations, the tower of soft graviton Ward identities is shadowed by the shadow connection $\{S_r\}_{r \geq 2}$ with soft order $p \leftrightarrow$ shadow arity $r = p + 2$:

$S^{(p)}$	Shadow	A_∞ source	Status	Physical interpretation
$S^{(0)}$	S_2 simple pole	m_2	Non-trivial	Weinberg
$S^{(1)}$	S_2 double pole	m_2	Non-trivial	Cachazo–Strominger
$S^{(2)}$	S_3/S_4	m_3/m_4	Gauge-triv. / non-triv.	CHY
$S^{(3)}$	S_5	m_5	Non-trivial	Conditional prediction
$S^{(p)}$	S_{p+2}	m_{p+2}	Non-trivial (p even)	Conditional higher shadow

For Virasoro at generic c , the tower is class M ($r_{\max} = \infty$): all $o_r \neq 0$ for $r \geq 5$, giving infinitely many algebraic HT-celestial shadow classes. Their interpretation as physical four-dimensional soft theorems is conditional and is not asserted here.

At large c (semiclassical): $S^{(0)}, S^{(1)}$ are exact ($O(G^0)$) in the shadow model; all higher shadow classes are suppressed by powers of $G = 3/(2c)$.

At $c = 26$ (critical string): $\kappa_{\text{eff}} = 0$ kills the genus tower, but the shadow connection persists ($S_4|_{c=26} = 5/1976 \neq 0$, etc.). Soft theorems are kinematic (genus 0); the genus tower is dynamical.

Question 70.5 (Universality across shadow depth classes). Heisenberg (class G, $r_{\max} = 2$): only Weinberg and subleading. $\hat{g}_k$ (class L, $r_{\max} = 3$): three soft-shadow classes. $\beta\gamma$ (class C, $r_{\max} = 4$): four. Virasoro and $\mathcal{W}_N$ (class M, $r_{\max} = \infty$): infinitely many. The shadow depth classification G/L/C/M mirrors the depth of the algebraic soft-shadow tower. Its interpretation as a tower of physical four-dimensional soft theorems is conditional on the celestial bridge and is not asserted here.
